CLINICAL LECTURE

ON THE NEUROTIC ORIGIN OF CLUB-FOOT, INFANTILE PARALYSIS, AND LATERAL SPINAL CURVATURE; AND ITS RELATIONS TO PROGNOSIS.

Delivered at the Pennsylvania Hospital

BY THOMAS G. MORTON, M.D.,

One of the attending Surgeons.

GENTLEMEN,—At our last meeting I promised that I would show you this morning some cases illustrating the results of nerve-lesions, especially upon the nutrition of the parts to which the nerves are distributed. Let me first direct your attention to the cases before you, which, however, are not strictly of the class of lesions of nerves. They illustrate, to a marked degree, atrophy following club-foot, atrophy not confined to the muscles, but involving all the structures, including the bone, as the result of impaired nutrition. The affected leg, as you see in each of these children, is poorly developed, and is less than the sound leg not only in its thickness, but in its circumference.

I believe that club-foot is the result of a cerebro-spinal defect,—that is to say, at some point in the brain or along the spinal cord there is a lesion which reduces the nerve-supply of a group of muscles, and subsequently impairs the growth of the affected part. During fœtal development, at some period, there has been a disorder of the nervous system which has produced the club-foot. I have seen nothing in my experience to warrant the idea that congenital club-foot has ever been caused by spasm of the muscles, or by position in utero.

In connection with a case recently before you (of pericoxalgia), I told you that whenever there is inflammation involving the nerve-trunk you must expect to have atrophy in the limb; not absolute, but relative, as compared with the other extremity. Remember to warn your patients of this, for it occurs in every case of well-marked hip-joint disease as the result of want of nutrition, and this condition will remain and cause more or less permanent deformity.

Wherever nerve-filaments are included in a focus of inflammation there will be a certain degree of sclerosis of the nerve, or a degeneration extending up towards the spinal cord. As a result there is defective nutrition, owing to central change, from extension of the process into the motor area in the anterior columns of the cord. The child may grow well elsewhere in all portions of its body, but the structures of the limb—the bone, muscles, and skin—show defect of growth. Of course, if you examine a case of hip-disease, you will not expect that you will be able in the very early stage to find this atrophy, but in the course of time it will become evident.

Let me show you this boy, 10 years of age, who came to me a year ago for treatment. I find upon applying the tape that the right leg measures around the calf ten and one-quarter inches; the left, barely nine and one-quarter inches. By noticing carefully the boy's feet, you will also observe the difference in the length of the feet, the right being nearly an inch longer than the left. This is not because he has had simply a disease of the bone,—for you will often find, after a resection of the humerus in which a large amount of the bone was removed, that the growth of the lower portion goes on as before,—but it is because there has been an inflammation which has affected the nerve-supply, a process of sclerosis in the nerve-trunk interfering with function. It might be urged that this atrophy has been caused by want of use; but that would not apply to the diminished length of the leg and foot.

I need hardly say to you that in a case of coxalgia, if you can arrest it in its early stage, with as yet very little inflammation of the surrounding structures, the result, as regards the future usefulness of the limb, will be better than if the disease had been allowed to go on. There will be a less amount of atrophy, and perhaps, if the nerve-trunk escapes, none at all. Therefore you should make special efforts to arrest the disease early, in order to secure the growth and usefulness of the limb.

This little girl, 12 years of age, had hip-joint disease about a year ago. The left calf now measures seven inches, the right seven and a half. A greater difference is found in the measurement of the thighs at the upper half, where it is an inch and a half. This is the usual history of a case

of this kind. The joint is at present entirely free of inflammation, although partly anchylosed.

Now we come to cases of infantile palsy. According to my experience, it is impossible to have infantile palsy of some duration without its being followed by permanent changes in the nutrition of the affected structures. A certain amount of nerve-degeneration takes place which is never repaired. The same condition exists, in effect, in club-foot, in serious inflammatory diseases of the large joints, and in infantile palsy. Will not the function be restored and the nutrition so improved in such cases by massage, electricity, and exercise, that the patient will get well? I say, no. The case may, and doubtless will, improve, but the affected limb will never bear a favorable comparison with its better-developed fellow on the opposite side.

This boy, 2 years of age, has a history like that of hundreds of others. At two years of age he had severe entero-colitis, lasting for some weeks. Afterwards infantile palsy occurred. Upon looking at the right leg, it is seen to be short: the bones have not grown to the same length as in the left. Now, it is simply impossible for this limb to develop like the other. In one we have a healthy set of nerves nourishing the limb; in the other there is evidently defective nutrition. I lay stress upon this, because if you do not warn the parents or guardians of the children that this must be expected, you will be blamed for it, and if a bad result follows it will be attributed to improper treatment. I find here (upon the right side) the calf is six and a half inches in circumference, and eight inches upon the other. The thighs show the same. One foot is warm, the skin looks red; the other foot is cold and blue, —a result of impaired circulation.

These cases, unfortunately, are apt afterwards to fall into the hands of quacks, who take the opportunity to throw blame upon the attending physician. The statement has been made that by putting the limb in a vacuum the case will recover. This is a fallacy: no such improvement can be hoped for.

In club-foot we have the instance of some nerve-fibres losing their functions, while others remain intact. Where we have the peronei muscles defective, the heel is lifted by the tendo Achillis, the inner border of the foot drawn upwards by the anterior tibial muscle, and the front of the foot twisted inwards by the posterior tibial and the long flexor of the toes, and varus is produced. If, on the contrary, the peronei are stronger, there will be talipes valgus; if the calf-muscles are unresisted, there will be equinus; if the extensor muscles are relatively stronger, there will be calcaneus or its compound forms. Although no spasm is present, yet the weak muscles yield to the stronger ones. Here palsy manifests itself in the peronei muscles, which are not much changed yet. But I find what we often see in many cases of infantile palsy: nature has thrown out material to protect the joint. We have a weak ankle, and nature throws out a great deal of dense fibrous material to make up for the weak ligaments, making the joint swell so as to look like a fracture or dislocation. The right calf is eight inches and the left eight and a half in circumference. If you should see this child a year from now, this difference will be still more marked.

This condition of defective innervation of muscles may be present at birth, and the case will then be called "congenital club-foot," even if the deformity be not noticed until some time afterwards. On the other hand, where the nerve-lesion is produced after birth by traumatism or disease and this deformity is the result, it is then known as "acquired club-foot."

The same principle of defective innervation extends to spinal disorders. In a case of ordinary curvature of the spine, where you have a set of muscles upon one side of the spine weaker than that upon the other side, you will have lateral deviation. This may occur in the course of only a few weeks. If proper treatment is begun early, the disorder may be arrested; but the same thing occurs as in other joint-inflammations: there is sclerosis of the nerve-trunks and resulting atrophy. In such a case you will find, upon examination of the arm and leg of the affected side, an actual diminution of size as compared with the opposite side of the body. This lateral deviation, let me say, is not a bone-disease, like the posterior curvature: it is simply due to a loss of strength and impaired nutrition in the muscles of one side of the body. This lateral curvature is not produced by carrying a weight or by leaning with one arm upon the table. Not at all. It is primarily a disease of

the nerves which emerge from the spinal column in the dorsal and lumbar regions, and the deformity results from weakened muscles,—the spine being pulled over, like a bow, by the stronger muscles of the opposite side. There is a convexity towards the weak muscles, and this is called the pathological curve; farther down there is a curve in the opposite direction, called the compensating curve. If you examine closely a case of lateral spinal curvature, you will always find this double or S-shaped curve.

Here is an adult woman who has been wearing an apparatus for relief from a lateral spinal curvature. Upon examination, there is evident diminution in volume of the mass of muscles upon one side of the spine; the arm above and below the elbow is considerably smaller than the healthy arm. This want of symmetry extends throughout this side of the body; even the mammary gland is smaller than upon the healthy side.

Therefore, lateral curvature of the spine, in most cases, and especially in youth, is simply the result of defective innervation, —which is worth keeping in mind in the treatment. We must be on our guard in the prognosis, and give the family of the patient notice that they cannot expect a perfect result where the nerve-supply is so decidedly defective.

ORIGINAL COMMUNICATIONS.

REPORT ON THE PROGRESS OF OTOLOGY.

BY CHARLES H. BURNETT, M.D.,

Professor of Otology in the Philadelphia Polyclinic.

ARTIFICIAL MEMBRANA TYMPANI.

DR. BARTH, of Berlin (*Archiv für Ohrenheilkunde*, Bd. xxii. p. 208, August 12, 1885) has suggested a very good modification of the ordinary cotton-wool membrane, as follows:

Take a piece of cotton-wool, and pull or twist out one end of it to the length of four centimetres, leaving a tuft at the other end. The handle thus made should now be dipped in collodion, and the whole, supported by means of the tuft through the mesh of a cane-seat chair, allowed to dry. In the course of five or ten minutes the handle or shaft should be again twisted, best with moist fingers, and there is then provided a strong shaft of cotton-wool one to two millimetres thick, with a brush-like tuft, which can be further trimmed by the scissors as required. This artificial membrane is so simple and so easily made that every intelligent patient can make it for himself if he is obliged to wear such an aid for any length of time.

OPERATIVE REMOVAL OF THE MEMBRANA TYMPANI AND THE TWO LARGER AUDITORY OSSICLES IN SCLEROSIS OF THE TYMPANIC MUCOUS MEMBRANE.

Prof. August Lucae, of Berlin (*Archiv für Ohrenheilk.*, Bd. xxii. pp. 235–242), has given his experience with this operation between the years 1880 and 1882. At the outset he states that his results have been of a nature to entirely cool his interest in the operation, which he might have anticipated *a priori*, in the opinion of your reporter.

It is interesting, however, to see to what lengths an operator will sometimes go in order to say he has done certain things. Lucae has performed the operation fifty-three times, on forty-seven individuals; six times on both sides. In all cases the hammer was removed, and six times the anvil was removed with the malleus. In all but five cases the operation was performed while the patient was under the influence of an anæsthetic.

The conclusions of this operator are that the operation is devoid of danger; but the results, so far as relief of tinnitus and deafness are concerned, are so unsatisfactory that he adheres now to the therapeutic means, and especially to passive motion by means of his "spring-sound."

THE ACTION OF COCAINE IN AURAL SURGERY.

Dr. F. Kretschmann, of Halle (*Archiv f. Ohrenheilk.*, Bd. xxii. p. 243), has kept careful notes for some time of all cases of ear-disease treated by cocaine in the clinic of the University of Halle. The cocaine has been used in all cases in five-per-cent. solutions of the hydrochlorate. The application has been effected either by instillation or by soaking cotton and passing the latter down the auditory canal upon the membrana tympani or upon some point chosen for incision. The period allowed for the application to take effect has not been less than fifteen minutes nor more than twenty minutes. In affections of the nares or naso-pharynx, the applica-

tion has been made by the camel's-hair brush directly to the spot to be anæsthetized, and this operation repeated two or three times, if necessary, at intervals of five minutes. The conclusions of the observer are as follows:

1. In operations on the membrana tympani, the anæsthetic action of cocaine (five-per-cent. solution) is uncertain.

2. In operations on the tympanic mucous membrane, cocaine has an anæsthetic effect. It fails, however, if the cut be deep enough to invade the subjacent bone.

3. In operations on the nasal mucous membrane, cocaine has both an anæsthetic effect and one which abrogates the reflex susceptibility.

4. In rhinoscopy, cocaine allays gagging and relaxes the soft palate.

In this connection, attention is drawn to the anæsthetic effect of brucine in painful affections of the ear, as first announced by the reporter in a paper read before the American Otological Society at New London, July 12, 1885, entitled

THE LOCAL USE OF COCAINE AND BRUCINE IN DISEASES OF THE EAR,

in which he stated an experience of negative results with cocaine as an anæsthetic in the ear, but reported very good results from applying five-per-cent. solutions of brucine to the ear. Its application as a local anæsthetic to the ear was tried in the Philadelphia Polyclinic at the suggestion of Dr. Thomas J. Mays. The solution employed was five per cent. of brucine, to which hydrochloric acid had been added in the proportion of five drops to the gramme; and in all the cases treated with this preparation of brucine the relief to pain had been prompt and complete, a result far more satisfactory than any obtained by him in the ear by solutions of cocaine. The applications to the ear were made by means of cotton on the cotton-holder, soaked with the solution of brucine.

Kirchner (*Deutsche Med. Wochenschrift*, No. 4, 1885) began with a two-per-cent. solution of cocaine, but found that nothing short of a twenty-per-cent. solution was sufficient to produce anæsthesia of the membrana tympani. But even with this the result is by no means sure,—an experience similar to that of Zauful (*Präger Med. Wochenschrift*, No. 7, 1885). The latter has had negative results in producing anæsthesia with solutions of cocaine in the membrana tympani; but he has found that in large perforations of the membrana the mucous membrane can be reached and anæsthetized by cocaine, so that granulations can be removed without great pain (*Archiv f. Ohrenheilk.*, Bd. xxii. p. 284, August, 1885).

INTRA-PETROUS GANGLIA OF THE AUDITORY NERVE.

Vulpian presented to the Académie des Sciences, March 24, 1885, for G. Ferré, an account of investigation on the above-named subject (*Annales des Maladies de l' Oreille*, etc., Juillet, 1885).

These ganglia are three in number: one is situated on the vestibular nerve (ganglion of Scarpa), the second upon the external fasciculus of the expansion of the cochlear nerve, and the third is arranged spirally the entire length of the lamina spiralis (this is the ganglion of Rosenthal or of Corti). All the branches issue from the auditory nerve and pass thence through a collection of ganglion-cells. This cellular mass or cushion is unique, as ganglionic nerve-cells are not found in the terminations of the auditory nerve. The three nervous ganglia thus form a zone of cells analogous to that found in the retina, probably to that composed of multipolar cells.

PSEUDO-MENINGITIS OF YOUNG DEAF-MUTES.

Dr. Boucheron, in the *Revue de Médecine*, May 10, 1885, under the above title has presented an account of a grave complication of otitis media in infancy (*Annales des Maladies de l' Oreille*, July, 1885). This consists in a destruction of the labyrinth-nerves by compression, the result of the forcing inward of the foot-plate of the stapes. The clinical forms of the otitis media are variable, sometimes being accompanied by general symptoms of a grave nature, as convulsions, coma, and fever, so that the physician might well suppose he had to deal with a meningitis, were it not for the fact that an otitis is always attended with deafness, and also were it not for a pathognomonic fact of differential importance,—that the inflation of the tympanum dissipates the alarming symptoms. In some cases the lesions occur without marked symptoms in the early months or years of life. The child, hitherto lively and intelligent, becomes suddenly dull and irritable, and loses its hearing. It ceases to learn to

talk, or ceases to use the speech it may have learned, and thus becomes a mute. This may be brought about without any marked symptoms or convulsive phenomena and fever, *so that one may be inclined to think such children deaf-mutes from birth, whereas their deaf-dumbness is truly an acquired one and consecutive to an otitis media.*

No matter what may have been the course of the symptoms, these children are deaf in proportion to the lesion of the internal ear, the result of compression. In almost all of them the membranæ are found sunken, and there are signs of naso-pharyngeal and tubal catarrh, the primordial cause of the disease. It is well known that the offspring of consanguineous marriages are often deaf and dumb. These unfortunates represent the confluence of diathetic naso-pharyngeal and tubal catarrhs of their progenitors, rather than cases of degeneration.

Treatment.—In respect to prognosis and treatment, it may be said the first depends largely on the second, which must consist primarily in treating the naso-pharyngeal catarrh, and in the use of tympanic inflations.

We must express great surprise at and disapproval of the suggestion of Dr. Boucheron to chloroformize all patients in order to insert the Eustachian catheter. It is quite as surprising and seems as unskilful as would be the suggestion to etherize the patient before introducing the vesical catheter.

ABSOLUTE UNILATERAL DEAFNESS FOLLOWING MUMPS.

Dr. Ménière (*Société Française de Laryngologie et d' Otologie*, April 2, 1885) reports two cases of deafness in one ear supervening upon mumps. He supposes that in all cases of deafness thus supervening upon mumps there is always a lesion of the meninges, the symptoms of which may be so evanescent, occurring at night, as to escape the attention of the friends and physician of the patient. He holds that the process is similar to that which he has observed in children who become deaf-mutes between the ages of one and five years, and in whom the cerebral involvement appears suddenly in the night, but is rapidly dissipated by morning. The event corresponds, in his opinion, with dentition.

AURAL DISEASE IN DIABETES MELLITUS.

The discussion of this subject is again broached by Kirchner (*Monatsschrift für Ohrenheilkunde*, No. 12, 1884), who claims that in this disease of the kidneys it is not uncommon to observe symptoms of catarrhal otitis media. It is usually consecutive to naso-pharyngeal catarrh, to which diabetic patients are generally liable. It may also arise, especially in the aged, from circulatory disturbances due to arterial sclerosis. The impaired vitality of the diabetic is used to explain the facility with which purulent inflammations arise in them, with their extensive and rapid effects.

An account of a case is then given, that of a young man, 22 years old, suffering from diabetes, and in whom there suddenly occurred in the right ear intense pain. There was found a marked otitis media, which necessitated a paracentesis of the membrana tympani. In the next few days there occurred a spontaneous rupture of the left membrana, which had been seen to be deeply congested at the time of the first examination. Suppuration continued in both ears until death occurred. Six weeks after the beginning of the aural disease there ensued a redness of the mastoid and a swelling from the tip of the latter towards the lower jaw, in consequence of which Dr. Kirchner felt justified in surgical interference. He met, at the point of the mastoid process, a small fistulous opening, which he made wider by chisel and gouge. Five days after the operation death ensued, being preceded by considerable sphacelus in the wound. The post-mortem examination showed that the right mastoid process formed one large cavity, and that the sigmoid fossa was perforated from the upper edge of the petrous pyramid throughout its entire length. On the left side the destructions were nearly of the same extent. Kirchner wisely advises to abstain from operating on diabetic patients except in the most urgent cases.

AUDITORY DISTURBANCES CAUSED BY EXPOSURE TO THE DISCHARGE OF FIREARMS.

Dr. Boucheron, of Paris (*Revue Mensuelle d' Otologie*, etc., May, 1885) has examined into cases of aural compression in adults, caused by the detonation of firearms. It is stated that very often the surgeon meets cases of deafness in those who have been

using firearms. In such cases it is held that at the moment of the accident—*i.e.*, at the moment of the impact of air from the concussion upon the membrana—there is an obstruction in the Eustachian tube. The concussion of the surrounding atmosphere induces sudden compression of that enclosed in the drum-cavity, and, secondarily, a compression of the nerves in the labyrinth. If the lesion be slight, the hardness of hearing is transitory; if it be more intense, the nerve-filaments are destroyed and the hardness of hearing is permanent. In those individuals exposed to analogous noises, such as boiler-makers, similar accidents are met with, but only where there is obstruction of the Eustachian tubes from precedent catarrh.

A prophylactic measure recommended consists in advising boiler-makers, artillerists, and those similarly exposed to great noises, to make efforts at deglutition (which tend to open the Eustachian tubes) before being exposed to violent noises or explosions.

The curative treatment consists in inflating the tympanum, in order to restore the membrana tympani to its normal position and thus put an end to the compression.

CHOLERA ASIATICA.

Read before the Microscopical and Biological Section of the Academy of Natural Sciences

BY W. XAVIER SUDDUTH, M.D.,

Director of the Physiological and Pathological Laboratory of the Medico-Chirurgical College, Philadelphia, Pennsylvania.

IT would be unnecessary and presumptuous for me to enter into any lengthy description of the ravages of cholera or its clinical history. Our knowledge in the past has been mainly confined to those phases of the disease. What I have to present to-night will in the main refer to some new light that has been thrown on its etiology; although there yet remains considerable to be cleared up with regard to discoveries which have recently been made.

Cholera is an endemic disease in India, and has repeatedly spread westward in the form of epidemics, none of which have exceeded its first advent in 1817, when it visited nearly every portion of the inhabited globe. It again made its appearance abroad, and first found its way to the United States, in 1832, and again in 1834. Subsequently it has visited our country in 1849, lasting till 1852; and again in 1866–67; and, lastly, in 1873. It is on its march again, and may reach here some time during the heat of summer.

One feature especially noticeable about its travels is that it has never shipped aboard the vessels rounding the Cape of Good Hope, or, doing so, it has worn itself out during the passage; the discipline, good hygiene, and regular diet subserving to good health during this long voyage and seeming not to form a suitable field for its propagation. Born and nurtured in the filth of the thickly-populated East Indian countries, it travels by short stages, following the lines of commerce, its spread being, beyond doubt, by actual contact. It is not carried by the trade-winds, nor is it contagious in the same sense as smallpox, scarlet fever, or measles. It is conveyed both by drinking-water and by food. History gives ample proof of its communicability by soiled linen, sewage, etc. It is a respecter of no age, sex, or condition in life. In its ravages it cuts down the rich as well as the poor; but its fatality is greatest among the intemperate. Its ravages are most marked in hot, moist climates, low rather than high altitudes, and the summer rather than the winter season.

Living in badly-drained, crowded cities, eating improper food, all manner of excesses, and mental depression, predispose to cholera. Lastly—and, I consider, *mostly*—is a previous epidemic of sporadic cholera dysenterica. Our British cousins learned this lesson long ago, and have profited by their knowledge: they instituted a strict surveillance over the city of London when it appeared, dividing it into districts in which physicians, officially appointed, were daily to visit and personally examine those living in them, and treat every case of dysentery found. Drawing their conclusions from the results obtained by this course of treatment, some English authorities are loud in their assertions that epidemic cholera is only an aggravated form of dysentery. It was an excellent line of procedure, and they builded better than they knew. We accept their treatment, but, in doing so, claim that it is only precautionary treatment and useful only in that it lessens the liability to infection.

For the propagation of any bacterium,

four things are essential: 1, a living germ; 2, depressed or decaying organic matter; 3, heat; and, 4, moisture. The germs of disease, micrococci, are ever present in the air we breathe, the water we drink, and the food we eat; and yet we live,—and why? Because not all the essentials for the propagation of disease are present at one and the same time in our bodies. Yet in your and my mouth to-night are probably germs that, if injected into the circulation, would cause death in a few days. The experiment of inoculating rabbits with normal human saliva has been tried often, and often resulted fatally. In normal epidermis and mucous membrane nature has provided a coat of mail against the entrance of these germs of disease into the circulation; but when these surfaces become abraded or their *vis vitæ* lowered from any cause, and the other essentials for the propagation of any specific germ that may be present are not wanting, then we have that special disease developed. When the germ-theory was first promulgated there were many who doubted, and there are yet, for that matter. They seem to clog the wheels of scientific progress, but in reality they only make the foundations of science firmer; and, although they may attain an ephemeral notoriety by boldly denying and demanding more proof, yet, in the end, the very opposition sets the true scientist to work to prove his views. Those who have been the leading believers in the germ-theory have had an especially hard hill to climb. If you take into consideration the small number of physicians who are experts in the use of the microscope, and then think of the vast number who have to depend on these few for their light in this investigation, it is really surprising that the theory has gained ground so rapidly as it has. It has had to fight every inch of the way. The masses of the profession have not been satisfied with the persistent discovery of the same form of bacilli in a certain disease, but he who found it must be able to cultivate it through successive cultures, and by inoculation on animals reproduce the disease.

Regarding the etiology of cholera, until the last twelvemonth all efforts to discover its specific cause, either in the air or in dejections of patients affected with cholera, had proved futile. The leading scientists of the day had to admit the plausibility of the application of the germ-theory in order to account for the origin and epidemicity of the disease. The germs evidently were capable of self-multiplication outside of the body; but all the known methods that could be brought into use for their demonstration failed to discover them.

The difficulties seemed insurmountable until Dr. Koch, stimulated by the oft-repeated failures of others, determined to go to Egypt and begin his investigations, and, if need be, follow the epidemic up to its home in India. He had not been long there until he reported that he had discovered a new genus of bacilli in the water-tanks of that country. Soon followed the finding of these in the intestines of patients who had died with cholera. He returned home, and began a series of experiments on animals with pure cultures. These results were negative at first, and he only partially succeeded in thus reproducing the disease.

When the epidemic broke out in France, it found Koch still hard at work trying to unravel the mysteries that surrounded its reproduction, by inoculation, on the lower animals. The French authorities sent for him to come to France, and, if possible, institute some methods that would ameliorate the ravages of the dreaded scourge. Soon after his arrival in Toulon a patient in the hospital sickened and died with cholera. This was a particularly favorable case for investigation, and, as the slide I have to show you to-night is made from a pure culture-solution obtained from this patient, the history of the case will interest you.

The patient was by occupation a sailor; had been admitted to the hospital for an attack of typhoid fever, but was convalescent, and was to have been discharged at noon. At 10 A.M. he was seized with cholera and died at 11 A.M., and within five minutes thereafter the autopsy was made and some of the contents of the small intestines examined. The same bacilli were found that had been previously discovered by Koch in India. Still the problem remained unsolved. Koch fully believed that he had made the long-wished-for discovery, but it remained to be proved. He cultivated this latter material up to the thirteenth generation, if I mistake not. In his experiments on the different media he found that the comma-bacilli (as he has termed them, from their resemblance to

a German comma) developed very characteristically on solid media, and liquefied the gelatin-culture media in a peculiar manner. They also grew very rapidly in bouillon, milk, serum, potatoes, and Japanese isinglass. Dr. Koch found out one very essential point in the culture of the comma-bacilli, and that was that the very greatest care must be observed in neutralizing the acidity of the bouillon, the presence of the least trace of acid being sufficient to prevent their development. In suitable media the comma-bacilli proliferate with remarkable rapidity at a temperature of from 86° to 102° F. They resist a very low temperature, +15° F. When the conditions are suitable for their development they multiply very rapidly, sometimes assuming the form of spirilla: in fact, they very much resemble the genus *Spirillum* in more ways than one. They are individually exceedingly short-lived. They also develop rapidly on soiled linen and in damp earth.

Koch's method of cultivating the bacilli is about as follows: "A small quantity of gelatinized pepton bouillon is inoculated with a little of the slime taken from the small intestine near its termination at the cæcum. The bouillon is then warmed until it becomes fluid, when it is poured on to a sterilized glass plate and spread with a sterilized glass rod. This is protected from the air by placing it underneath a bell-glass. The air within is kept moist by water-soaked blotting-paper. In a short time the colony develops, first as an irregularly-shaped pale spot on the surface of the gelatin. This soon assumes a granular appearance, and looks not unlike small particles of glass. As development progresses, the colony sinks into the gelatin, by reason of the liquefaction of the media. The colony then presents as a whitish spot under the surface of the gelatin."

At first Koch failed to reproduce the disease in animals, as he afterwards found, because of the acid condition of the gastric juice in health. He has now succeeded in producing the disease in all its virulence by ligating the pylorus and introducing the germs into the duodenum. The passing of the germs through the human stomach is accounted for by the fact that the gastric juice is not in its normal condition at the time of inoculation. To demonstrate the comma-bacillus in the tissues of the body, harden small pieces of the small intestine in alcohol and then stain in methyl blue. The bacilli will be found in the glands. They have never been found in the blood. They are quickly killed by drying. Koch's favorite method of staining them is with an aqueous solution of fuchsin. They are best examined with the aid of an Abbe condenser and a high-power objective.

Treatment is based on the following facts: first, the most probable source of contagion is the water-supply; second, the germs find a suitable field for development in the intestines of those who have had a previous attack of sporadic cholera; third, the presence of an acid is inimical to the development of the germs; and, lastly, long sea-voyages seem to militate against the continuance of the disease, hence the feasibility of quarantine.

From the foregoing we deduce the following suggestions as regards treatment, or rather prevention:

1. In the advent of cholera, all traps and drains should be overhauled, and a pure supply of water should be obtained. In the absence of ability to comply with the latter, none but sterilized water—that is, water which has been recently boiled—should be drunk. Ice should not be put in the water-pitcher, but the water-pitcher should be placed in the ice-box.

2. Careful attention should be given to the diet. Only such food should be eaten as does not tend to cause cholera morbus. All excesses should be avoided, and the first sign of dysentery should be noted and prompt measures adopted to check it. An acid lemonade composed of dilute hydrochloric acid and distilled water, in the proportion of six parts to thirteen, should be kept in the house, and may be taken *ad libitum*.

3. A rigid quarantine should be instituted on all incoming vessels from ports where the epidemic prevails. This quarantine should apply not only to passengers, but to freight also. No vessel should be allowed to discharge her cargo under thirty days. The laws regarding the importation and disinfection of rags should be rigidly enforced.

These deductions have been made not from personal experience in the treatment of the disease, but from a close study of the clinical history and the latest published facts regarding the comma-bacillus. The specimen which I have the pleasure of showing you this evening is from a pure

culture made by Koch himself. It is stained with fuchsin, and the bacilli appear in the form of short, curved objects, varying from one-eighth to one-half the width of a blood-corpuscle. They are magnified about seven hundred and fifty diameters.

A REPORT OF SIX HUNDRED CASES OF LABOR.

Read before the Philadelphia County Medical Society, September 23, 1885,

BY H. LEAMAN, M.D.

FROM the brief notes I have preserved of the last six hundred cases of labor which I have attended I have taken the material for the report which I now present to you, which, I hope, will at least have the merit of bringing some important topics before us for discussion.

The average duration of each labor was fourteen hours and forty minutes. The average duration of first labors, which numbered one hundred and eighty-seven, was twenty-two hours. Of these, there were five recorded of over thirty years of age, with an average duration of twenty-five hours.

The difference of opinion that exists on the duration of labor doubtless arises, as has been stated, from the difficulty in determining the limit of the first stage. There is a difference in women as to the accuracy with which they record their internal sensations. Some are cognizant of the slightest nerve-impression and can state it with exactness; others are dull and only aroused by a decided sensation, and are inaccurate in their report.

Multiparæ are very apt to be inaccurate in their statements as to the time of the onset of the first stage. They will very frequently reply, when questioned, that they have had slight pains for several days, but have taken no account of them. Primiparæ are more certain in their observations, as they are in a state of expectancy.

The length of labor has been counted, in all cases, from the first onset of dilating pain, which is generally felt in the lumbar, supra-pubic, or sacro-iliac regions, and is accompanied by dilatation of the cervix. The termination of labor has uniformly been carefully noted at the time of the delivery of the head.

The first stage of labor may be said to vary in length from two or three hours to two or three weeks. The second stage of labor is a more constant quantity, and extends in duration from half an hour to four hours. The first stage of labor is the process by which the uterus is prepared for the expulsion of its contents; the second stage is labor proper, and is a more definite quantity. Allowing two hours for rotation and two hours for dilatation of the perineum, we have four hours as the maximum limit for this stage. The exact time of separation of the limits of the first and second acts of labor cannot always be easily determined. The importance of distinguishing this stage, however, cannot be too earnestly urged, for it is at this point that mistakes are made and the forceps often injuriously applied. Full dilatation having occurred, delay beyond three or four hours may endanger both the fœtus and the mother.

The hour of day at which delivery occurs is worthy of note. In my list, out of six hundred cases, three hundred and nineteen were born between the hours of 6 P.M. and 6 A.M.; ninety-five were born between 12 midnight and 4 A.M.; one hundred and thirty-three between 4 A.M. and 8 A.M.; and one hundred and twenty from 8 P.M. to 12 midnight. The greatest number of births during one hour was forty, between 7 and 8 A.M.; the least was twelve, between 12 noon and 1 P.M.

Six hundred cases are too few to determine anything positively, but may be sufficient to draw an inference. The uterine force rises, falls, and rests. There would seem to be some relation between labor-pains and the pressure of the blood in the arteries. When labor is progressing in a strong, healthy woman, it may terminate any hour. But if there is a lack of easy adjustment between the pelvic environment and the fœtus, or an unfavorable presentation, then the arterial pressure comes into consideration. This is also indicated by the prevalent use of drinks during the progress of tedious delivery.

Position and presentation were observed in five hundred and sixty-eight cases, thirty-two being born before I was able to reach them. Vertex left front was present in three hundred and seventy-six; vertex right posterior in ninety-five; vertex right anterior in fifty-three; vertex left posterior in twenty-three; breech-presentations occurred in eighteen, face- in two, shoulder- in one.

Of the four hundred and twenty-nine vertex front presentations, two rotated into the hollow of the sacrum and were born vertex over the perineum; the remainder all rotated under the pubes. Of the one hundred and eighteen vertex posterior presentations, in one the chin dropped and became a face-presentation; twenty-one rotated into the hollow of the sacrum and were born over the perineum (ten of these twenty-one were delivered necessarily by the forceps); ninety-seven rotated under the pubes (of these only six were delivered with forceps). I am inclined to think vertex posteriors must have given rise to the invention of the forceps.

The forceps were applied in ninety-four deliveries. Twice they were applied because the obstetrician was compelled to hurry in order to attend to something else, although this ought never to be done; twenty-five times merely to aid in the exit of the head; in sixty-seven cases they were applied to relieve from painful and protracted labor. The reasons given for their use were contractions of the superior strait; large heads and bodies; firm heads with closure of the fontanels; obesity and weak abdominal muscles; and vertex posterior, particularly when rotation takes place into the hollow of the sacrum.

The breech-position was present in eighteen. Of these, eight presented sacrum to the back; sacrum to the pubes in four; sacrum to left in five; sacrum to right in one. Two of these were born dead.

There were two face-positions. One of these was born dead, but previously had been driven down in the pelvis for two or three hours by ergot administered by a midwife. The other was turned and delivered alive.

The sequelæ of these labors were rupture of the perineum in fifty-three: twenty-seven of these were slight, twenty-six were sewed with two or three sutures. Of these, twenty did well and healed perfectly. The usual efforts to prevent this trouble were used in all but twelve. These twelve were born in my absence. The rupture occurred uniformly with the head-position. In one case the tear was due to syphilitic warts, and in another to a large caruncle. Frequently it is caused by too rapid termination of the second stage of labor. Frequently the perineum itself is at fault, from a lack of development.

There were nineteen still-born children. Death was apparently due in two to prolapse of the cord; in one to too long use of ether; in two to too much ergot; and in one to convulsions. The majority were due to causes unknown. There were three cases of puerperal fever, and all died. One woman was taken with variola, miscarried, and died, at about the seventh or eighth month. One was taken with scarlet fever on the second day after delivery, and died on the eleventh day of the eruption. Four had metritis, one pyæmia, one mania. One had an intercurrent attack of facial erysipelas, but no metritis. Pleurisy occurred in one case. Inversion of the uterus took place in one case (it was not produced by the attendant): the symptoms were rapid fainting and severe uterine contractions. Post-partum hemorrhage was unknown in this series of cases.

This review, imperfect as it is, is presented in the attempt to elucidate some facts which are so familiar as to be overlooked. The most important fact connected with the subject of labor is the force exerted by the uterus in expulsion of its contents. The law of labor is the law of the uterus. The question for the obstetrician is not merely how to "get it out," but, under the circumstances, how the fœtus can best be born. The estimates of the force exerted by the uterus usually given seem to me to be exaggerated.

Meadows, for instance, sets down the involuntary or uterine force at 3.4 pounds to the square inch; voluntary or abdominal, as given by Houghton, 38.6 pounds. The two actions in labor seem to be direct and indirect. Their action is similar to that of the direct and indirect muscles of inspiration. The direct muscle is the uterus. The indirect are the abdominal muscles and diaphragm. We may add also accessory indirect, as muscles of the extremities and the thoracic muscles. The action of the indirect and accessory indirect is simply to fix the uterus and conserve its energy: the expulsive effort is applied by the uterus in such a manner as to impel the child, by gentle and vermicular movements, to elongate and mould its presenting part, and finally deliver it through nature's viaduct.

During the past year I have used a pressure-gauge with marked satisfaction. With it I have been able to determine when it was necessary to break the waters. It has enabled me to determine the complete

dilatation of the cervix. It also aids us in determining the necessity for forceps; and, in short, it gives exactness to our observation of a case of labor. The hand may determine the presence of heat in the fever-patient, but the thermometer alone gives definiteness to the idea of temperature. A skilled obstetrician may know the progress of labor, but dynamometry offers him greater accuracy in determining the rate of descent of the fœtus.

In my experience I have seen but once or twice a purely natural and physiological labor,—*i.e.*, the expulsion of the ovum in its entirety (placenta, child, and fluid in the unruptured membrane). Ordinary labor as described is a modification of this, although the essential elements are the same. There is the mass of the fœtus, flexible and readily compressible during delivery; the water first escapes, while the placenta, really separated with the other elements, is ready to follow immediately after the child.

828 North Broad Street, Philadelphia.

SUDDEN DEATH FROM ŒDEMA OF THE GLOTTIS.

BY W. J. JONES, M.D.,

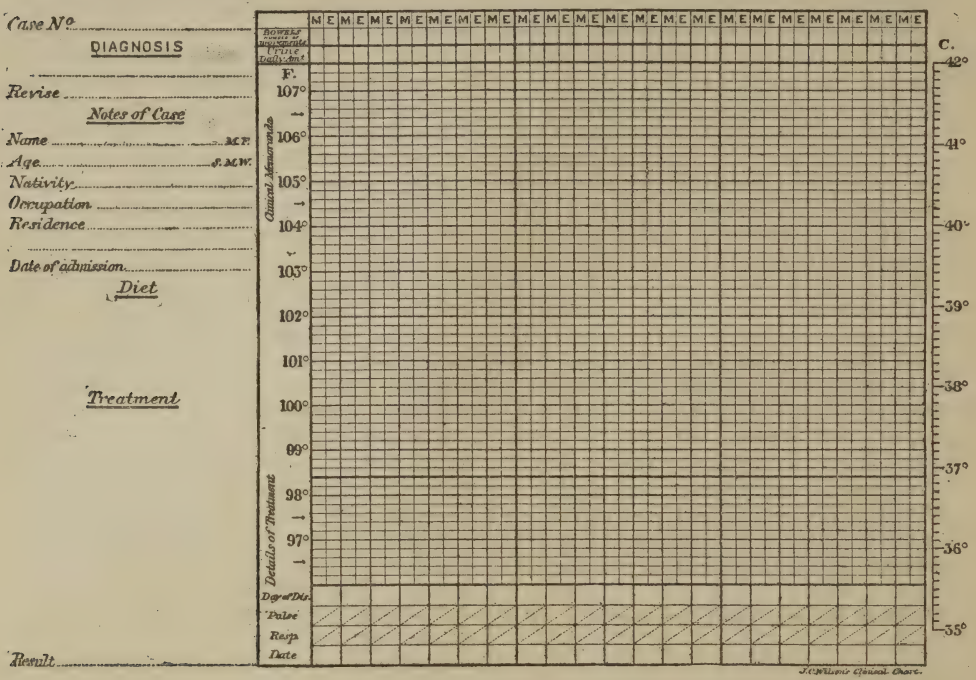
Resident Physician at Bay View Hospital, Baltimore.

THE following case will serve to show the clinical significance and pathological condition of œdema of the glottis.

J. B., colored, male, æt. 52 years, was admitted into the hospital at Bay View Asylum on the 24th of May last. He gave a history of having been a hard-working laboring-man, and the duties of his vocation often subjected him to considerable exposure. He was addicted to drinking a little too freely of alcohol at times, though not a constant drinker. He denied the history of any venereal disease. A careful physical examination of the patient showed that he was a large, well-built man. He gave no evidence of any disease of his lungs or heart. There was slight œdema of his lower extremities, which was not constant. An examination of his urine showed the presence of albumen and casts, and accordingly a diagnosis of morbus Brightii was made. Infus. digitalis was administered in ʒss doses thrice daily, and under its influence he seemed to improve until the morning of June 4, when, upon making my rounds of the hospital about ten o'clock, he complained of sore throat, inability to swallow easily, and slight dyspnœa. His lungs were examined, and air was found to enter freely. There was nothing to be seen in his throat to give alarm, though there was some slight swelling and redness about the fauces and the mucous membrane of the pharynx. The epiglottis, likewise, was red and thickened to some extent. Having no evidence at this time to lead me to suspect the fatal termination which so soon followed, I prescribed a simple gargle of potassii chloras, tinct. ferri chlor., glycerin, and water, and left him, promising to return again within an hour and make a more thorough examination into his condition. I was about to return to him at the time stated, when a messenger met me with the information that my patient was dead. An autopsy made a few hours after death showed the mucous membrane of the epiglottis and the entire larynx to be very much swollen and œdematous. This œdema reached to such a high degree as almost to occlude the entrance into the larynx. In the pharynx and on the posterior part of the tongue the follicles were somewhat enlarged; both lungs slightly adherent to the pleura at various places, otherwise normal; heart somewhat enlarged: left ventricle relaxed and dilated to some extent, valves soft; liver of ordinary size, and pale; spleen normal; kidneys of ordinary size, their capsules slightly adherent in places; the parenchyma hyperæmic.

The case is an important one from the fact of its rapid fatal termination and as to its cause. The suddenness with which the trouble began and the rapidity of its progress must be referred to one of the several causes of œdema of the glottis; and as our patient gave evidence both clinically and pathologically of morbus Brightii, and as œdema of the glottis may occur as the first and only dropsical affection connected with disease of the kidney, as stated by Flint, it is more than probable that the patient's kidney-disease was the prime factor in bringing about the cause which so suddenly terminated his life.

At the New Orleans Exhibition, the McIntosh Galvanic and Faradic Company received the first medal for fine display of electrical goods, and also the first medal for their combined solar microscope and stereopticon.



WILSON'S CLINICAL CHART.

DR. JAMES C. WILSON has devised a combined temperature-sheet and clinical chart, by means of which the daily records of the progress of a patient can be made at the bedside, while the chart, at the time of completion of the case, can be filed away for future reference. The advantages of noting important clinical facts in the presence of the patient, in the direction of accuracy and completeness, are too obvious to need discussion; while the convenience to the busy practitioner of having the records kept with the minimum of writing can scarcely be overestimated.

The plan of the chart, the dimensions of which are eight and a half by eleven inches, can be readily seen by a glance at the illustration (which is reduced to about one-fourth of the size of the original). The back of the chart is blank, so that the previous history and state of the patient when first seen may be entered, as well as the final note as to his condition when discharged; while the important facts of the clinical record and details of treatment can be written in the appropriate place upon the chart from day to day.

These charts are put up in tablet-form of fifty by the J. B. Lippincott Publishing Company. They have already been introduced into several Philadelphia hospitals, and have also been employed in private practice, where their usefulness is even more evident than in the wards of the hospital.

NOTES OF HOSPITAL PRACTICE.

MARYLAND WOMAN'S HOSPITAL, BALTIMORE.

CASES UNDER THE CARE OF PROFESSOR A. F. ERICH, M.D.

UTERINE HEMORRHAGE.

CASE I.—M. B., 22 years old, had been married since her fifteenth year; had had one child, five years ago; no miscarriages. Menstruation has always been profuse, lasting from five to ten days. For three months she had been bleeding almost constantly from the womb. She complained of pains in lower part of abdomen and pelvic region. The patient is stout and apparently in good health. The cervix was dilated by means of a sponge tent, and the interior of the uterus examined with the finger. Nothing abnormal discovered. Ten grains of nitrate of silver were intro-

duced into the uterine cavity and allowed to remain. The patient was placed upon house tonic (tincture of iron and quinine). The bleeding did not return, and in twelve days she was discharged well.

Case II.—A. S., 22 years old, married in her seventeenth year. Had been a widow for eighteen months. She had had no children and no miscarriages, according to her statement. Had almost constant metrorrhagia. Uterus retroverted and slightly enlarged.

A sponge tent, followed on the following day by a tupelo tent, enlarged the cervix sufficiently to permit an examination of the interior of the uterus with the finger. The mucous membrane was found covered with small, soft, fungous elevations, which bled readily on being touched. The patient was anæsthetized, and the uterine cavity thoroughly scraped out with a dull curette. Afterwards the cavity was swabbed with strong nitric acid.

On the following day there was a sanguineous discharge from the uterus, which soon ceased.

The patient was discharged from the hospital eight days after the operation. There was no return of the bleeding.

Case III.—J. W., 34 years of age. Had had two children and one miscarriage, last pregnancy terminating two years ago. Menses were always pretty free, lasting six to seven days,—being, however, regular in recurrence until the last three months, during which time the flow had been pretty nearly constant.

The uterus was enlarged and anteflexed, the cavity measuring four inches from os to fundus.

The cervix was dilated by sponge and tupelo tents until a finger could be readily passed into the cavity, when a rough mass was detected which was diagnosticated as the remains of a partially-retained placenta, which had become organized and firmly united to the uterine wall. Under anæsthesia this mass was scraped off with a blunt curette. Just before the operation the patient's temperature was 104.2°, which ran up to 105.2°. Under antipyretic treatment this was soon reduced, and on the second day afterwards the patient was cheerful, free from pain, and the pulse and temperature normal. On the twenty-second day after the operation the patient left the hospital well, and has had no return of the bleeding.

Case IV.—A. G. H., 38 years of age. Has been married sixteen years; had eight children and five abortions. Her last pregnancy terminated sixteen months ago. Her menstrual periods were regular until four months ago, since which time she has had constant hemorrhages.

The cervix was dilated with a sponge tent, and the dilatation completed by means of the finger. A blunt curette was then introduced, and a mass of tissue scraped away, which seemed to be the remains of placenta. The patient recovered without a serious symptom, had no return of the hemorrhages, and was successfully operated upon four weeks later for ruptured perineum.

Case V.—L. B., 33 years old, of large build, and well nourished. Had been married five years; had had one child and three abortions. There is reason to suspect that the abortions were intentionally produced. Since her last pregnancy terminated (in a miscarriage), five months ago, she had frequent profuse hemorrhages.

The cervix was dilated with a tupelo tent and the interior of the uterus scraped out with the dull curette. A large mass of tissue resembling spleen-substance was removed, being probably portions of retained placenta. The operation was done under ether, from which she recovered with slight nausea. Six days after the operation she was sitting up, and a week later left the hospital, having had no return of the bleeding.

The above cases illustrate a mode of treatment very frequently resorted to in this hospital,—*i.e.*, curetting the interior of the uterus in order to check uterine hemorrhage. In many cases, especially where the hemorrhage is an accompaniment of fungous endometritis, the cavity is mopped out with liq. ferri subsulphatis or with fuming nitric acid, preference being generally given to the latter. The after-treatment of endometritic cases consists generally of applications of silver nitrate in solutions of gradually decreasing strength, beginning with one to eight, and good food and tonics: iron, quinine, and strychnine.

THERAPEUTIC BREVITIES.

Many of the patients applying for relief at the out-door department of the hospital complain of vesical irritability, frequency

of micturition, with burning pain at the meatus and much straining. In a large proportion of these cases the urine is alkaline and frequently cloudy. These symptoms are usually quickly relieved by the following combination:

℞ Acidi benzoici, ʒj;
Sodii biboratis, ʒjss;
Aquæ, fʒvj. M.

S.—Tablespoonful every three to four hours.

If the trouble does not yield to this medicine, Dover's powder in three-grain doses every two to three hours is frequently found effective.

As a tonic in the anæmic condition so often attendant upon the pelvic troubles of women, the following pill is given:

℞ Quininæ sulphat., gr. xlviij;
Ferri sulphat. exsic., gr. xxiv;
Strychninæ sulphat., gr. i. M.

Ft. pil. xxiv.

S.—One after each meal.

The operations for lacerated cervix are generally done in the hospital without an anæsthetic. A catgut loop is passed around the cervix and drawn tight by means of a wire-écraseur frame. This not only renders the operation a practically bloodless one, but the strangulation of the tissues obtunds the sensibility, and the denudation can be completed and needles passed without causing more than a slight degree of pain.

TRANSLATIONS.

SOME OBSERVATIONS ON URTICARIA OCCURRING IN INFANCY.*—Prof. Bouchard, in his researches upon dilatation of the stomach, has observed that a certain number of these patients are subject to more or less annoying outbreaks of urticaria. It is not at all surprising that a disease which has for its principal and immediate consequence faulty elaboration of the ingesta should awaken cutaneous manifestations like urticaria, when we see temporary digestive disorder (*embarras gastrique* and indigestion) accompanied by the same eruptions. This urticaria due to lesions or functional disorders of the stomach (like those which supervene after tapping hydatid cysts) is very probably a toxic urticaria due to the fact that the skin serves as a route of elimination to the poison elaborated in the digestive passages and taken up into the circulation. This, at least, is the rational explanation which M. Bouchard gave to this phenomenon in a paper recently read before the Faculty of Medicine.

Dr. Comby tried, in a certain measure, to apply to the infants coming under his observation the results which were obtained from adults by Prof. Bouchard. The dilatation of the stomach, encountered so often among the latter, Dr. Comby had found with almost equal frequency among infants of the poorer classes, subjected from birth to defective alimentation. Among animals, also, he had found, as a consequence of dilatation of the stomach, multiple disorders in many of the organs and tissues.

The diverse eruptions grouped by authors under the name of "*gourmes*" (porrigo, scald-head, etc.—TR.) appear with extreme frequency in little patients with dilatation of the stomach; but, of all these eruptions, that which had struck him most by its objective and subjective characters is urticaria, of which he reports five cases. Two of these have been previously published in a memoir upon "Dilatation of the Stomach," the last three are new.

Case I. Boy of Three and a Half Years; Artificial Feeding; Rachitis; Chronic Urticaria; Dilatation of the Stomach.—A pale, thin child, sufficiently large for his age; nursed by his mother, but was not able to walk until fifteen months old; at the age of six months he took solid food; he often had attacks of vomiting, and had green and offensive-smelling stools. The abdomen had always been large; it presented along the linea alba the projection so often found in rachitis. It was easy to demonstrate the dilatation of the stomach; the churning or splashing extended to the level of the umbilicus. The infant drank a good deal. The mother brought the child on account of an extremely obstinate skin-eruption, extending over the entire body and reappearing at intervals since the age of six months,—that is to say, from the moment when the infant commenced to swallow other food besides the milk. These attacks of urticaria had been accompanied by much itching, which lasted several days, and which returned in

* Communication read before the Clinical Society of Paris by Dr. J. Comby. Translated from *La France Médicale* of August 25, 1885.

a severe form in spite of all the treatment employed. At certain times and seasons the eruption was more or less marked. Upon admission, his entire body was covered with urticarial wheals and lesions caused by scratching. It seemed perfectly legitimate to attribute this urticaria to the dilatation of the stomach, and it was hoped that treatment of the dilatation would act favorably upon the cutaneous manifestation. In fact, under the influence of dieting, and principally the suppression of the excess of liquid which the infant had been allowed to swallow, the chronic urticaria of three years' standing was completely cured.

Case II.—Girl of 19 months; improper feeding; chronic urticaria; dilatation of the stomach.

Case III.—Girl of 3 years; bottle-fed; rachitic; dilatation of the stomach; urticaria.

Case IV.—A child 25 months of age; bottle-fed; dilatation of the stomach; urticaria.

Case V.—A girl of 2 years; improper feeding; rachitis; dilatation of the stomach and urticaria.

[In these cases generally the symptoms resembled so closely those of the first case, and the results of treatment were so nearly identical, that they need not be given in detail.—Tr.]

The above cases belong to early childhood, from nineteen months to three years and a half. All of them, before the outbreak of urticaria, had presented grave and prolonged digestive troubles, which led naturally to dilatation of the stomach and rachitis. The first two were affected with the chronic form of urticaria, the most chronic and rebellious to treatment. The last three were cases of acute or subacute urticaria, coming within the class of what authors have described as "urticarial fever."

It is evident that the incessant and obstinate attacks of urticaria were in relation with the digestive disorders which the infants presented, and that the dilatation of the stomach was concerned in their causation. They were not the kind of urticaria which Bazin called pathogenetic, because this is provoked by the ingestion of certain articles, such as mussels, shellfish, lobsters, spoilt fish, etc. Besides, the little patients had not been subjected to an alimentation which could explain the urticaria; only the imperfect elaboration of food consequent upon dilatation of the stomach could be assigned as the cause. Treatment without attention to the disordered digestion will be unsuccessful for such cases; baths and topical agents will be used in vain; but, on the contrary, if we treat the dilatation of the stomach by dry regimen, the cure of the urticaria follows.

When attacks of urticaria occur in children, we should at once seek for disorder in the digestive tract, and in particular the stomach. Possibly dilatation of the stomach may also be found. For, among infants even more than among adults, the skin is reactive to the disturbances or functional disorders of the digestive tube. Under the influence of repeated attacks of indigestion, we see the bodies of young infants covered with eruptions, as if the cutaneous surface served as emunctories for the toxic matters elaborated in the digestive tract. These eruptions, weeping and covered with scales, will be replaced later by dry papules, by eczemas, or by attacks of urticaria. The cause of the cutaneous manifestations is always the same; the form alone is modified.

Dangers of Antithermic Remedies.—In a recent therapeutical conference, Dr. Dujardin-Beaumetz discusses resorcine, kairine, thalline, and antipyrine, and advises caution in their use, of the first three agents especially, from their active toxic effects. After referring to the eminently antiputrefying and antifermentive properties of resorcine, he states that he had used it in pyrexia without obvious effects, probably on account of the smallness of the dose. He finally abandoned it altogether in the treatment of rheumatism and typhoid fever, not so much on account of its want of power as because he observed toxic symptoms. Resorcine is not only an irritant, it is also a toxic agent; and in his experiments upon dogs it was determined that a dose of thirty centigrammes per kilo of weight of the animal produced convulsive phenomena, and death was caused when the proportionate dose was increased to ninety centigrammes. After death, visceral congestions were discovered, and especially very intense pulmonary engorgement, as in animals poisoned by carbolic acid. Man is even more susceptible to the effects of

resorcine than dogs. Munel reports a case in which a single dose of three and a half grammes (fifty-three grains) rapidly induced a condition of great gravity, which, however, was finally overcome.

Dr. Beaumetz says, "While recognizing resorcine as less toxic than phenic acid, I conclude that it is a dangerous antithermic agent, for I found in my typhoid patients treated with resorcine the same depression of forces, the same adynamia, the same pulmonary congestion, which I had found in those to whom I had administered phenic acid. I have therefore abandoned this medication, and I believe that, even in Germany, resorcine is not much employed internally, but it remains, on the contrary, a very valuable remedy for external use in the treatment of unhealthy wounds."

Kairine is an antithermic acting by diminishing the respiratory power of the blood and destroying hæmoglobin. The recent researches of Brouardel and Paul Loye confirm this view, and show that thalline and kairine exert the same destructive effect upon hæmoglobin. Moreover, contrary to the usual action of antithermic agents, kairine and thalline have no influence whatever upon fermentations. "Kairine should therefore be rejected from therapeutics; it is a dangerous drug, since it only produces antithermic effects by destroying the hæmoglobin and profoundly altering the blood, circumstances which should be avoided in the infectious febrile diseases."

Antipyrine is less toxic than either resorcine or carbolic acid. While it takes a gramme of resorcine per kilo to kill a rabbit, it takes 1.60 gramme per kilogramme of antipyrine. The toxic effect, moreover, is almost the same; it produces tetanic and paralytic symptoms analogous to those caused by strychnine-poisoning. It cannot be doubted, therefore, that antipyrine acts upon the cerebro-spinal axis, and it is probable that it lowers the temperature by modifying the nervous heat-centres. Contrary to kairine, antipyrine does not appear to change the liquor sanguinis, and particularly the hæmoglobin. It has also hæmostatic properties which Henoch declares superior to those of ergotine and of chloride of iron. (This is worth bearing in mind in treating hæmoptysis.) Antipyrine diminishes the urinary secretion, but increases the action of the glands of the skin, which renders it inconvenient to use it in cases of tuberculosis. Like the phenols and oxyphenols, antipyrine is an antiferment. The study of recent antithermics shows that the effects of these new agents vary with the nature of the fever: a temperature of 104° in a phthisical patient will be lowered by fifty centigrammes of antipyrine, while in a typhoid case it might be without effect. —*Bull. de Thérapeutique*, August 30.

Hypertrophic Rhinitis.—In his Thèse de Bordeaux (1885), Dr. Fontanilles discusses the treatment of rhinitis hypertrophica, which he defined as consisting in a swelling, general or local, of the nasal mucous membrane. The general causes are scrofula, syphilis, herpetism, chronic coryza, and acute coryza. The local causes are of special importance in the pathogeny. At their head he places an immoderate size of the openings of the nares, which admit large currents of air bearing irritating solid particles, which increase proportionately with the force of the current. The absence of hairs, the use of snuff, and the use of cold nasal injections too frequently, he names among the causes of hypertrophic rhinitis.

The functional symptoms are those of nasal stenosis. The progress of the disease is slow, and, according to certain authors, it is only an intermediate step towards atrophic coryza. It may be complicated with disturbances of olfaction, loss of smell, and difficult breathing. Hearing and sight may be affected, and there may be reflex disorders.

The diagnosis should be made between this condition and tumors of the nasal cavities, rhinoliths, foreign bodies, adenoid vegetations, and especially polypi.

The treatment is both constitutional and local; the first is directed to the diathesis, and the second consists in cauterizing the mucous membrane with galvano-cautery or chromic acid: he suggests that the preliminary application of cocaine may be useful.

From a study of several cases at the clinic of Dr. Moure, the author concludes as follows:

1. Hypertrophic rhinitis is not merely a symptom, but a morbid entity perfectly determined.

2. It must not be confounded with chronic coryza, naso-pharyngeal polypi, or adenoid vegetations.

3. The complications, sometimes serious, merit particular attention.

4. Its treatment, always successful, consists in the application of the galvanic cautery or crystallized chromic acid.—*Revue mensuelle de Laryngologie, d' Otologie et de Rhinologie*, No. 9.

Local Venous Circulation of the Fingers.—By following a new method of injection, in which the fluid is thrown into the veins towards the extremities, Bourceret has succeeded in demonstrating most beautifully the venous radicles and their relations to the capillaries and arterioles, in the hands and feet especially. Following the process of Bourceret (of placing the member in warm water, after a preliminary colorless injection into the main artery to distend the vessels), the large venous trunk is then opened and a canula inserted, then, in both vein and artery simultaneously, two injecting-fluids differently colored are forced until the smallest vessels are filled. The subsequent dissection reveals the delicate ramifications and final distribution of arteries and veins in a striking manner. The capillaries of the pulp of the finger display a remarkable arrangement. An arteriole of relatively large size may be seen to become suddenly broken up into a plexus of capillaries and form glomerules, which proceed to form venules. These glomeruli are seen principally upon the palmar aspect of the last phalanx, under the anterior two-thirds of the nail and on the thenar and hypothenar eminences.

At all these points, besides this special (tactile) circulation, could be seen the usual circulation of nutrition, of which the vessels presented the usual type. The veins of the fingers rise for the most part from the last phalanx. Then radicles unite almost immediately to form trunks of relatively large size. From thence they proceed longitudinally along the back of the finger, forming a subcutaneous vascular layer without forming irregular plexuses, but with frequent anastomoses.

In fact, there exists at the points named a special functional circulation, distinct from the circulation of nutrition, characterized essentially by the large calibre of the vessels out of proportion to the nutrition. According to M. Bourceret, this special circulation has for its object the giving of aid to the circulation of nutrition and of keeping the parts warm. It may also have something to do with the exquisite sensibility of these regions.—*Le Progrès Médical*, No. 35.

Pathology of Tetanus.—Dr. Arrigo Maroni ("Un Caso di Tetania," Milan, 1885, and *Le Progrès Médical*), having observed mydriasis and inertia of the pupils in a case of tetanus coincident with the access of spasm of the muscular system, and occurring independently of any alteration of the tissues of the eye, as well as from certain physiological reasons, has been led to entertain new views with regard to the pathology of tetanus. Without going into the details of this interesting communication, the conclusions are as follows:

1. The site (and the central organ) of the neurosis in question is found in the gray substance of the spinal cord, and more particularly in the cilio-spinal zone, without excluding, however, the medulla oblongata.

2. A periodical morbid stimulus developing itself in this gray matter, and exalting the physiological activity of different groups of cells therein contained, will provoke, by predominant excitation of the motor groups, paroxysmic muscular contractures; by excitation of the sympathetic centres, spasmodic mydriasis; and, affecting to a certain point the sensory tract, it will provoke divers disorders of sensibility, local or general, preceding or accompanying the access.

3. The cause of the morbid stimulus probably resides in the variation of blood-pressure within the spinal cord due to a reflex action upon the vaso-motor nerves in consequence of an irritation affecting the peripheral branches of the sympathetic or of the sensory nerves.—*Le Progrès Médical*, No. 32.

Erysipelas.—In a communication read before the Académie de Médecine, MM. Trélat and Verneuil insist upon the importance of antiseptic treatment, and urge the isolation of cases occurring in hospitals. M. Cornil said that the difference in gravity between medical and surgical erysipelas is due to the fact that in the former the bacterium of erysipelas exists alone, while in the latter it is combined with the micro-organisms of pyæmia, and that in the latter class of cases it occurs in patients already weakened by previous sickness or traumatism.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, OCTOBER 3, 1885.

EDITORIAL.

THE NEW VOLUME.

THE *Philadelphia Medical Times* enters upon its sixteenth year of publication with a larger number of subscribers and readers than at any previous time in its history, thus demonstrating very satisfactorily that its course meets the approval of the profession.

During the current year it is the intention to continue the special features which have hitherto given value and interest to its pages. Original communications, reports of rare and interesting cases, notes of successful treatment, and especially hygienic and sanitary reports, will always receive early attention, and if possessing general interest will be published as early as possible. Authors of papers written for this journal will receive reprints of their articles, if desired, or an equivalent in money at the time of publication; and we invite our readers to communicate such facts or observations as they think interesting and useful, and capable of contributing to the progress of our art.

In deference to the suggestion embodied in several communications, it has been decided to retain the title of *Philadelphia Medical Times*, chiefly in order to prevent confusion with journals of the same name in other cities, and to retain credit for abstracts taken from our pages, although in view of the scientific and non-sectional standing of the *Times* it would be preferable to drop the portion of its title which might be construed as implying that its interests are local or limited.

The thanks of the editor are heartily tendered to the contributors, correspondents, and collaborators who have so faithfully performed their work in the volume just completed, as well as to those who have promised to continue their valuable assistance for the coming year.

RECENT EXPERIMENTS REGARDING THE EFFECTS OF TEMPERATURE UPON THE FILTRATION OF ALBUMEN.

THE physical conditions controlling the rapidity of filtration and affecting the relative quantity and character of solutions of albumen passing through animal membranes have been recently investigated by several observers. Although the question is still too recent to warrant drawing formal and final conclusions, yet results have been obtained of considerable interest in their relation to physiological and pathological problems now engaging professional attention.

Dr. Adolph Loewy* has reported the results of a number of experiments instituted with the special object of determining the influence of temperature upon the filtration of albuminous solutions through animal membranes. The results obtained by him have special significance in their bearing upon the appearance of transitory albuminuria during pyrexial states, and the occurrence of exudations and serous effusions. W. Schmidt had previously published (in *Poggendorf's Annalen*, Bd. 99, p. 350) the reports of a series of experiments upon the quantity and character of the filtrate as affected by pressure, concentration, combination, and temperature of the original solution. Although aqueous solutions of salts were employed, as a rule, he subsequently reported a few observations upon filtration of gummy and albuminous solutions also (*idem*, Bd. 114). Runeberg has more recently communicated the results of

* Ueber den Einfluss der Temperatur auf die Filtration von Eiweisslösungen durch thierische Membranen.—*Zeitschrift für Physiologische Chemie*, vol. ix. Heft 6, Strassburg, 1885. A bibliography of the brief literature of the subject is appended to Dr. Loewy's paper.

experiments instituted to determine the influence of different conditions upon the rate of filtration. The temperature, however, has been a factor which hitherto has not had the attention given to it which its intrinsic importance deserved. Some observers had only noted it in an endeavor to secure a uniform condition for their experiment, others appeared to have overlooked it entirely. At the suggestion of Prof. Senator, Dr. Loewy undertook to investigate this point, and, by making use of an ingenious filtering apparatus designed for the purpose by Dr. Herter, was able to get results which to a certain extent contravene those of Schmidt and Runeberg, whose methods are criticised in the communication referred to, and a course of experiments detailed, the conclusions deduced being as follows:

1. The quantity of the filtrate increased with the temperature. The higher the degree of temperature, the more the filtrate.

2. The residue (after heating the filtrate to dryness in a water-bath), in its *absolute* quantity, was also increased by the high temperature; and here also the rule is, the greater the temperature the more the increase.

In the greater number of cases, the *relative* quantity in high temperature was also proportionately large.

3. The absolute amount of the organic constituents of the filtrate shows a greater or less increase, corresponding with a greater or less degree of temperature. The percentage or *relative* value is, in high temperature, likewise increased in the greater number of cases.

4. The inorganic constituents, as the temperature is raised, appear in greater quantity in the filtrate. However, the increase of temperature had less influence upon them than upon the organic, since their relative quantity was reduced in the greater number of cases.

These experiments may possibly throw some light upon the difference in the relative proportion of albumen existing in transudations and exudations,—the greater amount of albumen in the latter during the fever-process being connected with the more easy filtration of the albumen in higher temperature. Although under normal conditions the urine is almost entirely free from albumen when first secreted, yet there are numerous pathological conditions attended by an increase of albuminuria. In explanation of those in which fever occurs these experiments find direct application, although other factors doubtless enter into the pathological problem besides the merely physical ones of heat and pressure.

COMPULSORY VACCINATION IN CANADA.

IT is with apprehension and regret that we receive the intelligence of the riots in progress in Montreal against the enforcement of the Compulsory Vaccination Act, which went into operation September 28: apprehension, because the existence of an epidemic of smallpox on our border makes us deeply concerned in the efficiency and promptness of the methods used to control it; and regret, because it is a serious matter for a community to require to be forced to do that which its physicians believe to be necessary for the public health. While it is universally admitted that a man in becoming a member of a community is obliged to submit to some restrictions, it is by no means uniformly settled by law or custom just how much of his personal liberty he thereby does surrender. It is hoped that the time will eventually arrive when all men will do what they ought to do of their own volition, but until the dawn of the millennium the problem of enforcing right by might will continue to puzzle the physician, the moralist, and the statesman. It is expedient and necessary that all should submit in the emergency of an epidemic to extraordinary measures for the preservation

of public health, and vaccination affords protection from smallpox at such slight sacrifice of physical comfort that every one when required should, by personal example and influence, endeavor to have it universally performed.

In the presence of an epidemic the municipal and State authorities might at once order the vaccination of all the attendants and inmates of State institutions, hospitals, asylums, and prisons; of children in the public schools; of all immigrants, as well as vagrants or criminals arrested upon the streets, and also all who apply for the operation. Houses in which smallpox prevails should be isolated, and no one allowed to go in or come out without complying with the requirements of the Health Board. But when we come to the compulsory vaccination of healthy families in the absence of disease in the household, the terms of the problem are slightly altered, and this question is one that should engage the serious and careful consideration of both legislator and physician. The medical profession, in this case, is a friend both of the court and of the claimant, and in this position can do much towards creating a healthy public sentiment upon sanitary measures, and thus aiding the enforcement of measures required for the public health. In a free country ignorance is better taught, than fought.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

I HAD hoped to be able to give some account of the discussion on glycosuria at Cardiff in this letter, but have been disappointed by the non-publication of the details: it must, therefore, stand over till a future letter.

The next most important medical matter of the present time is Dr. Goodhart's Bradshawe Lecture at the Royal College of Physicians, on "Morbid Arterial Tension." This should have been delivered by the late Dr. Mahomed, whose work in connection with the subject is so well and so widely known. Some account of him and his labors was given in a recent letter.

Dr. Goodhart, who is Senior Assistant Physician and Lecturer on Pathology at Guy's Hospital, commenced with a fitting tribute to the departed man in whose stead he stood. After this he plunged into the subject, with which he manifested great familiarity. He commenced with the late Dr. Bright; but it is known that, long anterior to his day, Dr. James, of Exeter, had observed that there was a tight pulse without hypertrophied left ventricle—without any valvular disease—in certain cases; and this he attributed to some impurity in the blood which impeded its outflow through the small vessels. Dr. Bright found coexistent kidney-disease, and regarded the impurity in the blood as nitrogenized waste,—a view now generally entertained. He put it: "Either the altered quality of the blood affords irregular and unwonted stimulus to the organs immediately, or it so affects the minute and capillary circulation as to render greater action necessary to force the blood through distant subdivisions of the vascular system." The subject has been worked out at length by Prof. George Johnson, of King's College, who has written so well on disease of the kidneys. He expounded a stop-cock theory of arteriole contraction, cutting off the supply of impure blood to the tissues.

While this exposition has undoubtedly attracted much attention to the subject, I cannot help feeling that this fanciful explanation has stood in the way of its acceptance by many. Dr. Goodhart holds the balance just and true when he says, "Fully examined, there is not much objection to that way of stating the case; but there is just a touch of fancy in the stop-cock simile, which provokes the criticism that it smacks too much of a purposive volition." He then gave what Dr. Dickinson has said of this view: "The heart and arteries are thus represented as acting in antagonism and hypertrophied by the efforts each makes to get the better of the other."

Dr. Goodhart thinks this not unphysiological, and that Dr. Bright did well to stick to the clinical facts. He pointed out that where resistance is to be overcome, organic muscular fibre develops to meet the occasion, as seen in the intestine when there is a stricture, in the walls of the bladder when it experiences a difficulty in emptying itself; and the same occurs with the heart. "In all these instances we see simple illustrations of a common physiological principle admitted by all." The question, he said, is, "Is the muscular coat of the arterioles thickened in chronic renal disease?" To this he replies, "Not so much by a demonstration of the fact, which is perhaps not so easy as it might at first sight appear; but by an appeal to the entirely *a priori* ground that it must be so." Dr. Johnson always argued that there must be resistance

offered at the arteriole end in order to set up high arterial tension and an hypertrophied left ventricle. He showed the hypertrophied muscular fibre under the microscope previous to as well as in that notable conflict between himself on the one part and Sir William Gull and Dr. Sutton on the other part, before the Medico-Chirurgical Society in 1870.

Dr. Goodhart holds that "appeal to demonstration, and to demonstration only, in the present day is too absolute. No doubt it is, on the whole, the safest ground to tread, but appearances admit often of various interpretations;" while, within such limits as its present use, he believes his argument to be unassailable.

As regards the existence or non-existence of spasm in the arteriole-wall, he raises the question whether the muscular walls of the arterioles do not really help to propel the blood by a vermicular action. If such is the case, then arterio-capillary fibrosis or degeneration of this muscular coat would lead to arrested blood-flow, and so we get an hypertrophied left ventricle, with degenerate walls in the arterioles. This view has been upheld by several men who have worked at the subject. He said, "In withstanding the increased blood-pressure it surely must count for something, if it be but the pygmy to the giant." There can be no question about the clinical fact that there is a linked condition of a tight artery, an hypertrophied left ventricle, an accentuated aortic second sound, and a large flow of urine, the physiological associate of high arterial tension.

He then adduced the analogy of the action of digitalis, which "is said to increase the strength of action of the muscular wall of the heart on the one hand, of the arteries on the other." If Rosenstein is right,—and few will call his statement in question,—"digitalis empties the veins and fills the arteries." Consequently it increases arterial tension. About its direct effect upon the heart, no one who has watched a dilated heart contract under its persistent use until a distinct amount of hypertrophy of the left ventricle is induced can doubt that part of the argument. That it also prevents the rapid outflow of blood from the arterial system is a matter few will call in question who have had much experience of its use. In one of the few cases where its toxic effects were brought out in my experience, the pulse was hard and the action of the heart violent and hammering; indeed, a condition was set up precisely analogous to that of the high arterial tension of Bright's disease.

As to the question of spasm, Dr. Goodhart says, "It is clear that a muscular action which leads to hypertrophy might easily pass into spasm under conditions similar to but in excess of those which have provoked the increased action." We see in angina pectoris vaso-motoria, common with the gouty heart, an instance of a condition of passing spasm implanted upon one of hypertrophy of the two muscular ends of the vascular system. He continues: "Indeed, the assumption of some such spasm, if not necessary, is at any rate agreeable to many of the phenomena of Bright's disease. I may instance the headache and the renal asthma, both of which are sometimes much relieved by nitrite of amyl and nitro-glycerin, drugs which unquestionably relax spasm and promote dilatation of the peripheral vessels."

Having thus discussed Dr. Johnson's views, which find remarkable support in the evidence furnished by the sphygmograph, he turned to the arterio-capillary fibrosis of Gull and Sutton. It is not generally known that Dr. Handfield Jones wrote on this subject considerably anterior to these two later investigators. Their position, according to Dr. Goodhart, is this: "Old age is not an entity, but a set of conditions predisposing to that state which is called chronic Bright's disease." He continues: "And while to most this comes in natural order when the prime of life is over, yet to some old age is no matter of years and averages, but the running down of a spring set for an individual. It comes at times even to children. In the tints of summer—yes, even in those of spring—you can read old age if you will. And although chronic Bright's disease is in many cases associated with renal disorder, it is not essentially a matter of organs; the generalizing change in the tissues of the whole body is the essential, and to some this comes not by kidney chiefly, but by lung chiefly, by brain, by heart, and so on." It is with the greatest possible pleasure I write what Dr. Goodhart has put at once so happily and so pithily.

As long as Bright's disease is a matter of the presence of albumen in the urine, so long will the medical man's mind be like a closed fist, which, as Rufus Lyon justly said, "is shut up from receiving and holding aught precious, though it were heaven-sent manna" ("Felix Holt"). So long as a deceptive error is firmly planted across the path to knowledge, no progress can be made except by those resolute enough to cross the barrier somehow. For the man who emancipates himself from the demoralizing superstition, a broad expanse of knowledge spreads itself out before him; and such good, honest teaching as this of Dr. Goodhart's ought to do much to encourage men to get to the farther side of the barrier, and see in what we call "Bright's disease" something larger, something more extensive and wide-spread, than kidney-mischief solely,—and that is not mere albuminuria. Of course the simplicity of boiling urine in a test-tube recommends itself to many minds as much easier than a thorough acquaintance with a wide-spread and complicated morbid process in its complexity as well as with each individ-

ual detail. He cleverly describes this change as "a magnificent scheme of decay," and says of it, "The idea is a suggestive one, and it is largely true. Pathology is distinctly the richer for it, but it derives its strength less from the labors of the histologist than from the bird's-eye view, the intuition—may I call it so?—of experience. There is ground in plenty for the argument that we wear out by tissues or systems; there is, I think, a fair amount of evidence admitting the opinion that chronic Bright's disease, with contracted kidney, is a generalized degeneration; but to base it upon the non-existence or unimportance of muscular hypertrophy of the arterioles, and to ascribe the thickening which exists to an essentially hyaline fibroid degeneration, is equivalent to the unskilful selection of a battle-field." Then he proceeds: "How far, then, do I think it is true? Perhaps an answer to that question may best be arrived at by continuing upon the other, How far is it not true? And, going to the other end of the circuit, there are groups of cases which admit no doubt in which the disease in the kidney is certainly the cause of the changes in the heart and arteries." He has collected a number of cases where parenchymatous nephritis was the morbid starting-point, and changes in heart and arterioles followed therefrom. As to how quickly perceptible hypertrophy of the heart can be developed, the change is often more rapid than is assumed. (I remember Prof. Traube, of Berlin, discussing this question in La Charité, Berlin, and giving it as his opinion that perceptible changes may be set up in a few weeks,—five, in one case.)

Dr. Goodhart says, "A large series of observations may possibly throw some light upon the moot point, the rate at which the heart can put on muscle; for the heart has been found large in some cases in which there was every probability of the renal disease having existed but a few weeks." He then discourses of a very practical matter: "Such differences as do exist between the two classes of cases are of more practical moment than of worth as distinctions. For, in the first place, it may be said that the failure of health and of nutrition will not unfrequently combine so to reduce the arterial tension as to deprive the circulatory system of the excuse for hypertrophy. The danger, too, in these cases is much more serious at any one time than the granular kidney can show. The left ventricle has, in consequence, more tendency to dilate, and thus to relieve the excessive tension and forestall the hypertrophy by the death of the patient. I put it thus pointedly as a fact of importance. In proportion as the renal disease is sudden and severe, so is the risk of dilatation of the heart. The more insidious it is, the more likely is the cardiac hypertrophy to be present in greatest perfection. Serious acute renal disease means sudden increase of arterial tension and the imposition of greatly-increased labor of the heart, and rapid dilatation of the wall becomes a serious risk." Bravo, Dr. Goodhart! Concentric hypertrophy of the left ventricle is not the only cardial change, though some seem to think it is.

I have long insisted that the cardiac change will be a blend of hypertrophy and dilatation, according to the rapidity of the demand upon the heart and the nutritive powers of the system. In "Gout in its Protean Aspects," page 49, is written, "When the nutrition of the tissues is defective, then, instead of hypertrophy, dilatation is the consequence of a high blood-pressure in the arterial system." There is another misleading superstition scotched, if not slain. In a recent letter I gave some details of a case where a heart fairly hypertrophied yielded after two severe attacks of angina pectoris vaso-motoria, and a condition of dilatation was set up in a very short time. In speaking of the relation of this condition of high arterial tension to atrophy, Dr. Goodhart says, "It is obvious that dilatation of the heart is unfavorable to the occurrence of apoplexy. It relaxes the tension at the centre which would otherwise be put on at the periphery, and death comes about by cardiac failure, and not by peripheral hemorrhage." Then, in looking at the matter from a clinical stand-point, he continues: "It is worth remembering, for it cannot be unimportant whether the risks of an individual are those of apoplexy or of the more gradual process of cardiac failure; and the undoubted value of a drug such as digitalis in many of these cases is a ready criterion of the importance of the point in the matter of treatment." Right again, Dr. Goodhart. In the one case you materially increase the danger of the large heart bursting an artery, in the other you strengthen a failing heart.

Then the lecturer proceeded to discuss the hyaline fibroid changes found with the large left ventricle. The gist of what he said, and said well and convincingly, is as follows: Where a tendency to tissue-growth is set up in a complex tissue like an arteriole-wall, "the least specialized or less dainty feeders are likely to have the best of it and to supplant the more highly specialized. . . . Therefore I see no contradiction in the fact that in the tissues and vessels of chronic renal disease the muscle may be thick in some parts, wasted in others, or that the vessels can be recognized as well by the hyaline fibroid thickening of the coats as by the muscle." When we remember that overstrain or high arterial tension is the exciting cause of atheroma, it is not difficult to conceive of change in other tissues than the muscular. "Hence, as the direct outcome of the overwork, we might expect more or less excessive nucleation of the coats of the arterioles, and ultimate fibrosis." This point is insisted upon by Dr. Dickinson.

As to the production of cardio-vascular changes in renal disease, he said, "It is only in cases where the excretory area is disproportionately small for the body-weight that the effect must be sought. If the body waste and the heart fail, the kidney may be small indeed, yet sufficient for its day,—just as the chronic phthisic could not possibly have lived on had not the progressive wasting compensated the balance. It is also true that the general changes may be extreme, and the kidneys but a little granular or coarse."

What Dr. Goodhart has to say upon albuminuria as connected with Bright's disease is short, and to many no doubt eminently unsatisfactory. Indeed, it is difficult to discern what is his real attitude upon the matter. It is instructive, in the present state of medical feeling on the subject, that he devotes so little space to the subject, and what little is said is put cautiously. "I suppose that ever since Bright's time it has been felt by all that albuminuria must often be but a rough and a late test of disease, and that there are conditions preceding it which, if we could recognize them, would tell us more."

Then he went into the subject of the sphygmograph and its revelations. It "told us, in one sense, what we knew before, but it told its tale with a graphic interest which had much the merit of a new discovery." What it tells is of increased arterial tension, and supports "the hypothesis advanced and supported by Dr. Walshe as early as 1849, that Bright's disease is not renal, but primarily a blood-disease." He next pointed out the frequency of dilatation of the pulmonary artery in cases of prolonged high arterial tension. In conclusion, it may be said of Dr. Goodhart's lecture that it was in every way worthy of the occasion, and a demonstration that the school of which Bright and Addison were but recent factors, despite dark days, is still vital and active, and holding its place in the van of medical progress. No doubt the lecture will soon appear in pamphlet-form, in which many will be glad to renew their acquaintance with it.

J. Milner Fothergill.

BALTIMORE.

Baltimore, September 14, 1885.

For the past seven years the Medical and Chirurgical Faculty of Maryland has had its meeting-rooms and library in a building part of which was used as a patent-medicine factory. Members on going to the rooms would see directly in the entrance-way a sign one could not help noticing, setting forth in large and conspicuous letters the virtues of "New Life," an unfailing cure for consumption and all lung-diseases. This has been a source of much complaint among the members; but it is only recently that steps have been taken to remove the library to more commodious and respectable quarters in the Athenæum Building, corner of St. Paul and Saratoga Streets. The new rooms were formerly occupied by the Mercantile Library. In the same building are the valuable library and art collection of the Maryland Historical Society. The library of the Faculty is constantly increasing in size and value, and the large number of current journals upon the tables makes it one of the best working medical libraries in the country. Unfortunately, the Faculty has no permanent home, but is at the mercy of landlords. Some years ago a beginning was made to raise a fund for a medical building, but only a small sum was collected, and the enthusiasm of a few who started it seems to have entirely fizzled out.

The preliminary lectures of the winter session begin to-day at the medical colleges here. The prospects for large classes are favorable.

The Baltimore Medical College, one of the younger institutions, has put on a spurt. A hospital was secured last winter, and a handsome new college-building has just been completed. The majority of the members of the present faculty are young and energetic, and promise to deserve success.

Owing to impaired health, Prof. Richard McSherry will be unable to deliver his course of lectures on the Principles and Practice of Medicine in the University of Maryland this winter. His place will be filled by Prof. Chew, and the course on Materia Medica and Therapeutics will be given by Prof. I. E. Atkinson.

It is rumored that Prof. Matthew Hay, of Edinburgh, has been elected Professor of Pharmacology in the Johns Hopkins University. By this appointment five of the chairs in the future medical department of this university have been filled. These are Physiology, Chemistry, Pathology, Hygiene, and Pharmacology. The incumbents of the four first-named are, in order: Dr. H. Newell Martin, University Professor of Biology; Dr. Ira Remsen, University Professor of Chemistry; Dr. William H. Welch, formerly Pathologist to Bellevue Hospital, New York; and Dr. John S. Billings, U.S.A., who will lecture on public hygiene.

Dr. George M. Sternberg, U.S.A., has been ordered by the State Department to return to Rome as the delegate from this country to the International Sanitary Conference, which reconvenes in November. Dr. Sternberg has just been elected an honorary member of the Royal Academy of Medicine in Rome.

G. H. R.

Agaricine, in doses of one-sixth of a grain, to be repeated if necessary, is an efficient remedy for excessive perspiration, and there appear to be no disagreeable or undesirable effects attendant upon its use.

PROCEEDINGS OF SOCIETIES.

THE AMERICAN GYNÆCOLOGICAL SOCIETY.

THE Tenth Annual Session was held in Columbian University, Washington, D.C., September 22, 23, and 24, 1885.

TUESDAY, FIRST DAY—MORNING SESSION.

The meeting was called to order by the President, Dr. William T. Howard, of Baltimore.

Dr. Samuel C. Busey delivered the address of welcome to the Association as the guests of the Washington Obstetrical and Gynæcological Society.

The first paper, by Dr. Samuel C. Busey, of Washington, was entitled

THE NATURAL HYGIENE OF THE CHILD-BEARING LIFE.

Although pregnancy is to be regarded as a physiological process, yet Dr. Busey regards it as one which terminates with more or less injury to both mother and child; it is impossible to define the border-line of health and to say where the physiological ends and the pathological begins. The age of greatest safety coincides with the age of greatest fecundity; beyond and below this period the mortality increases with the difference in age. The fifth quinquiniad is the period during which the laws of fecundity, nubility, and survival find their natural complement in relatively the highest perfection. Precocious maternity is to be deprecated, but in this country and in the higher walks of life precocious matrimony seems on the increase. To this evil he desired to direct general attention.

The discussion was participated in by Drs. Chadwick and Reynolds.

Dr. Henry J. Garrigues, of New York, read a paper on

PUERPERAL DIPHTHERIA.

The speaker had met with twenty-nine cases of this affection. It is one of the different diseases included under the term puerperal fever, and is characterized by diphtheritic infiltration somewhere in the genital canal of the puerperal woman. The situations in which the vagina narrows, and the posterior wall of the vagina, are the parts most commonly affected. Five of the twenty-nine cases died, and in all of these the autopsy showed the uterus much larger than it should be. Its walls were thickened and softened, sometimes almost diffluent. In some cases the muscular tissue has been scooped out, as is seen in dissecting metritis. Anything that weakens the patient, as well as injuries to the genital tract, predisposes to the affection. The cause of the disease is, however, infection from the outside, and this infection appears to be carried from one patient to another by the air of the ward.

The first symptom is usually the occurrence of fever two or three days after delivery. There are at times chills or chilly feelings. The temperature, as a rule, varies three or four degrees from the normal. Examination shows the uterus larger than it should be, and quite tender. The lochial discharge is often scanty. The diphtheritic patch makes its appearance from three to seven days after delivery.

The diagnosis is not difficult. The affection is to be distinguished from the grayish discoloration of abraded surfaces following the use of corrosive sublimate, and the sloughs produced by the application of chloride of zinc in the treatment of this disease.

The prognosis is doubtful. Five out of twenty-nine cases died, giving a mortality of 17.2 per cent. When the diphtheritic process is checked, recovery is usually rapid. The duration of the disease, when it ends in recovery, averages two weeks.

To prevent the development of the disease, the vaginal examinations during labor should be as few as possible. Neither the finger nor the hand should be introduced into the uterus unless it is absolutely necessary. Wounds of the genital organs should be avoided, and instruments should be used with care. The most important element is, however, antisepsis with bichloride of mercury. Everything that comes in contact with the genital organs should be disinfected with a one- to two-thousandth solution of corrosive sublimate. Since he had adopted this method, the speaker had seen but one case, and that was where a resident physician had delivered a woman immediately after removing a macerated fœtus from another patient.

The plan of treatment which had given the most satisfaction had been applications of a solution of equal parts of chloride of zinc and distilled water, applied to the diphtheritic patches; and, as the application is painful, an anæsthetic may be used. Where the uterus is involved, warm intra-uterine injections of corrosive sublimate solution (1 to 2000) are employed; and, following this, a suppository of fifteen grains of iodoform is introduced. The intra-uterine injection needs to be repeated only once in the twenty-four hours, but the vagina should be douched with the same solution every three hours. If after twenty-four hours the diphtheritic process is not arrested, the application of chloride of zinc is to be repeated. If the disease be limited to the vagina and vulva, the intra-uterine treatment is to be omitted. Such remedies as are indicated by the general symptoms are given internally.

The speaker then exhibited the occlusion-bandage which he uses after labor. This consists of a pad of absorbent cotton, to be placed against the vulva; over this he places a piece of waxed muslin or rubber-cloth, and

outside a pad of cotton. The whole dressing is treated with the bichloride of mercury solution and secured to the binder by means of a strip of muslin or cotton flannel. The doctor then referred to the great decrease in mortality following the introduction of this treatment. Previous to its adoption, the death-rate had been nearly seven per cent. It was now less than three-fourths of one per cent.

Dr. W. T. Lusk, of New York, and Dr. W. L. Richardson, of Boston, had used the method of Dr. Garrigues with success.

Dr. John Byrne, of Brooklyn, described an interesting case in which vaginal deformity by cicatricial tissue followed puerperal diphtheria.

FOUR CASES OF OÖPHORECTOMY, WITH REMARKS.

This was the title of a paper by Dr. Joseph Taber Johnson, of Washington.

The first case was that of a woman, aged 29, who for fourteen years had suffered with chronic oöphoritis and menstrual epilepsy. After the failure of all other treatment, both ovaries and one Fallopian tube were removed. The patient made a good recovery, and for several months had no periods and no spasms. Gradually the menses returned, and with them the spasms to a slight degree.

The second case was that of an unmarried woman, aged 21. For five years she had chronic inflammation of the ovaries following suppression of the menses from cold. The ovaries and tubes were removed, and the patient is now well.

The third case had been a great sufferer with dysmenorrhœa and reflex symptoms. After four months' treatment, oöphorectomy was performed, and the patient recovered and continues well.

The fourth case was a married woman, aged 40, the mother of several children. She had complained of a pain in the left ovary for twenty years. She was practically bedridden for three weeks out of every four. She insisted on an operation, although she was advised to postpone it for a few years longer until the occurrence of the menopause. The ovaries and tubes were removed. She did well for three days, but vomiting then appeared, and she died on the sixth day.

DISCUSSION.

Dr. R. S. Sutton, of Pittsburg, advocated the performance of an exploratory operation in these cases where the seat of the disorder appears to be the ovaries or tubes, even when the disease of these organs cannot be demonstrated.

Dr. W. H. Baker, of Boston, thought that there was danger of this operation being performed too often. An operation which gives such brilliant results in properly-selected cases, is apt to be abused. If in an exploratory operation the ovaries and tubes are found to be healthy, so far as their gross appearances are concerned, they should not be disturbed.

Dr. T. A. Emmet protested against the too frequent performance of the operation. There are some cases in which it is indicated, but these are rare. He thought that it should never be done for dysmenorrhœa, which he considers a neuralgic condition dependent upon anæmia. Where dysmenorrhœa is relieved by the operation he believed it to be attributable to improvement in general nutrition rather than to the mere removal of the ovaries.

The paper was further discussed by Drs. Lusk, Reamy, Jenks, and Mann.

WEDNESDAY—SECOND DAY.

The first paper, the President's address, on

TWO RARE CASES IN ABDOMINAL SURGERY,

was read by Dr. William T. Howard, of Baltimore.

The first case was as follows. A negress, aged 24, married, presented herself at the Dispensary of the University of Maryland, April 26, 1882. She was the mother of five children, and had never had a miscarriage. Menstruation was normal and regular. The last child was two months old. Shortly after this confinement she observed an enlargement in the lower part of the abdomen. Examination showed well-marked fluctuation all over the abdomen, with distinct resonance around the umbilicus, with dulness and bulging in both flanks. Six weeks later the umbilical resonance had disappeared. Two weeks later she was seen by Dr. Howard for the first time. She was then evidently quite sick, with a temperature of 102°. Physical examination revealed the presence of pleurisy. Crackling râles were found throughout the lungs. The abdomen was of about the size of seven months' pregnancy, and remarkably protruding in the centre. There was complete dulness over the tumor, and resonance in the flanks. The area of dulness was unchanged by variation of position. All the signs of a unilocular cyst were perfect. The uterus was found well in front of the cyst, and the sound entered two and two-thirds inches.

The next question was as to diagnosis. Ovarian cyst was excluded by the infrequency of this affection in the negro and by the rapid development of the tumor. Fibro-cystic tumor of the uterus was excluded by the great rarity of the disease and its extreme rarity before the age of thirty-five years, the rapid growth in the present case, and the absence of menstrual disturbance. Parovarian cysts are usually of slow development, are apt to be flaccid, are comparatively rare, and do not affect the general health. This was therefore excluded. Simple ascites was excluded with-

*

out difficulty. Encysted dropsy of the peritoneum was next considered. This, in the early stages, is accompanied with symptoms of constitutional disturbance. The abdomen is not prominent, and often flaccid. This was therefore excluded.

On June 20 the speaker aspirated the abdominal cyst, and removed a light, straw-colored fluid which speedily coagulated. The patient did well for three days, when acute peritonitis appeared, and she died on the seventh day.

At the autopsy a large mass, consisting of the omentum, the transverse colon, and small intestine, bound together by inflammatory exudation, was found. This formed a cavity in which the fluid had collected. The peritoneum was everywhere invaded with miliary tubercles. There was tubercular ulceration in the small intestine. The other abdominal organs were not affected. There was also tubercular pleurisy, and throughout both lungs were scattered gray miliary tubercles. This was then a case of encysted tubercular peritonitis, presenting the character of an ovarian or a parovarian cyst.

Case II.—F. R., aged 24, complained of a heavy weight in the abdomen, which was greatly enlarged. There appeared to be an immense unilocular cyst. This had begun seven years previously, and the increase in size had been gradual and not accompanied with pain. The length of time which it had lasted was against its ovarian origin. The length of time that it had been developing, the marked fluctuation and the flaccidity of the cyst, were in favor of a parovarian cyst; but the fact that the tumor could not be impressed below the umbilicus was against this view. Fibro-cyst of the uterus and encysted peritonitis were excluded. The diagnosis lay between an ovarian and a parovarian cyst.

An exploratory operation was decided upon. The peritoneum was much thickened, and closely adherent to the cyst. A trocar was introduced, and forty pints of fluid escaped. It was impossible to enucleate the sac. The opening in its wall was therefore enlarged, and on looking into its interior it seemed as though all the abdominal organs had been removed, the cyst-wall being stretched tightly across the spinal colum. A drainage-tube was introduced, and the wound closed. The patient died of acute peritonitis. A satisfactory post-mortem was not obtained, so that no further light was thrown on the nature of the case.

DISCUSSION.

Dr. Emmet said that while in the case described yesterday he objected to exploratory operations, yet in these cases of tumor he advocated it, for the woman had something that should be taken away. He had seen a case resembling the second one described in the paper. He was obliged to leave the sac. This was washed out frequently, and in six weeks had greatly diminished in size. Strangulation of the intestine then occurred, and the woman died.

Dr. William Goodell thought that in many of these cases it was very difficult to make the diagnosis even after the removal of the tumor. He favored exploratory incision.

Dr. T. A. Reamy had seen a case of encysted tubercular peritonitis in which the patient died on the second day after the removal of the fluid. He also described cases showing the difficulty of diagnosis.

Dr. W. T. Howard, in closing the discussion, said that in the majority of cases a diagnosis could be made. The cases that he had described were instances of rare affections. They had been cited to facilitate the diagnosis of similar cases.

Dr. T. A. Reamy, of Cincinnati, read a paper on

THE CARE OF THE PERINEUM DURING LABOR.

After referring to the many methods in use for the support of the perineum during labor, he described a method which he had used for several years. When the perineum begins to bulge, the patient is placed across the bed, with the limbs in the lithotomy position and the knees close together. A towel or bandage ten inches wide and a yard and a half long is placed around the buttocks and perineum, with the upper edge of the bandage on a level with the fourchette. The ends of the bandage are given to two assistants, who sit on each side of the patient, or, if the bed is narrow, they take their positions at the head of the patient. They are told to make traction during each pain. The accoucheur sits in front of the patient and sees that the traction is made in the proper direction. Care must be taken that the towel is smoothly applied to the perineum. The forceps may be used with the towel in position. This method is comfortable to the patient, and does not necessitate exposure.

Dr. Chadwick said that he had been in the habit of using the method practised in Vienna, which consists in having the patient on the side, with the accoucheur sitting by her side. He then passes one arm over the thigh, and, interlocking the fingers with those of the other hand, is able to make any desired amount of pressure on the advancing head, thus delaying it until the perineum is thoroughly stretched. He is careful that the head shall not be born during a pain.

Dr. Ellwood Wilson, of Philadelphia, stated that the only plan he employed was to see that the woman kept her mouth open during the last pains.

Drs. Reamy, Wilson, Mann, Johnson, and Reynolds also took part in the discussion.

Dr. Sutton objected to the method referred to by Dr. Chadwick that it had a tendency to

cause premature extension of the head, thus increasing the peril of the perineum.

Dr. Edward W. Jenks, of Detroit, reported

A CASE OF CÆSAREAN OPERATION.

The patient was a well-proportioned woman, 27 years of age, in her second labor. The first labor had not been particularly difficult, and had occurred five years previously. Two years later she had sustained a fracture of the right ilium, which was the cause of difficulty in the second labor. Labor began at three o'clock in the morning, and the physician was called. As there seemed to be some difficulty, he attempted to apply the forceps. One blade was readily gotten in place, but the second could not be introduced, and then the projecting ridge of bone was discovered. A second physician was called, who also failed to apply the forceps. A third was called in consultation, and the forceps were again tried. Craniotomy was then decided upon and performed, but the head could not be brought down.

Dr. Jenks was then telegraphed for, and arrived at the house at 9 P.M. In order to be certain that it was impossible to apply the forceps, he made the attempt, but was unable to introduce the second blade. Neither could the cephalotribe be introduced. It was then decided to perform abdominal section. This was done at 2 A.M., nearly twenty-four hours after the beginning of labor. The woman was, however, in good condition. When the uterus was cut through, the placenta was found attached immediately beneath the cut, and the bleeding was alarming. Delivery was rapidly accomplished and the hemorrhage stopped. The uterine wound was brought together with silk sutures and the abdominal incision closed. The patient reacted well and did nicely until the third day after the operation, when—the nurse leaving the room in disobedience to orders—the patient got out of bed, was seized with a severe pain, and died in the course of twenty-four hours.

DISCUSSION.

Dr. Skene, of Brooklyn, thought that laparo-elytrotomy would have been better suited to this case.

Dr. Jenks said that laparo-elytrotomy had been considered, but the other operation preferred. The patient would probably have recovered if it had not been for the unfortunate accident.

Dr. Ellwood Wilson, of Philadelphia, made some

REMARKS ON THE USE OF TARNIER'S FORCEPS.

At a previous meeting the speaker had presented a number of objections to the Tarnier instrument. Since then he had used the forceps in several cases with advantage, and he wished to correct the statements which had been made on theoretical grounds. A detailed account of nine cases in which the Tarnier forceps had been used with benefit was then given.

He had used the modification of the Tarnier forceps devised by Dr. William T. Howard, of Baltimore.

Dr. Niell, of Baltimore, presented his modification of the Tarnier forceps, which consisted in adapting the Tarnier principle to the Simpson forceps in such a way that the traction bars could readily be detached.

The paper was discussed by Drs. Parvin, Goodell, Mann, Wilson, Howard, and Reamy.

THURSDAY, THIRD DAY.

Dr. R. Stansbury Sutton, of Pittsburg, described

A MODIFICATION OF EMMET'S CERVIX OPERATION, WITH A CASE.

While the operation was original with the speaker, he did not claim to have been the only one who had performed it. In every case of lacerated cervix which has lasted for any length of time, the lips of the cervix are indurated and covered with cicatricial tissue, which greatly interferes with coaptation of the lips in performing the operation. This cicatricial tissue is especially abundant in those cases in which nitrate of silver applications have been employed. The condition may be limited to one lip, or it may affect both.

The case described was operated on in June, 1885. She was 42 years of age, the mother of several children. There was a double laceration of the cervix, and the anterior lip was much hypertrophied and as hard as cartilage: it was convex from side to side as well as from before backward. The posterior lip was denuded in the ordinary manner, with the exception that the median strip of mucous membrane was left wider than usual. The anterior lip was denuded clear across, and all the cicatricial tissue removed. The lips were then united in the ordinary manner. The result had been excellent. A probe could be readily passed, and the patient menstruated without difficulty.

DISCUSSION.

Dr. Goodell had employed this method in some cases. He had also at times outlined the strip of mucous membrane corresponding to one side of the new cervical canal and dissected it from the indurated tissues below, which were then removed. The strip of mucous membrane was then brought in place and the lips treated in the ordinary way. This had given a good result.

Dr. Skene, instead of using the method described by Dr. Sutton, had been in the habit of performing a preliminary operation to get rid of this indurated tissue. This consisted in removing a transverse, wedge-shaped piece from one or both lips as might be required,

and bringing the surfaces together with silk stitches. After the size of the cervix had been reduced, the ordinary operation was performed. This had given good results.

Dr. George J. Engelman, of St. Louis, had in these severely indurated cases paid no attention to the retention of the median strip of mucous membrane, but denuded both surfaces completely across and brought them together. In the position of the future canal he placed one strand of carbolized silk thread. After the removal of the sutures, the passage was dilated with the probe. This operation has been followed by a perfect result so far as union, involution, and the health of the patient are concerned.

Dr. Mann had also employed the method described by Dr. Sutton.

Dr. Baker considered that the retention of the strip of mucous membrane was of importance, and thought that Dr. Emmet's operation could always be done in these cases by adopting the suggestion of Dr. Skene. He, however, preferred to do both operations at one time.

Dr. William Goodell, of Philadelphia, read a paper on

INFLAMMATION OF THE PAROTID GLANDS FOLLOWING OPERATIONS ON THE FEMALE GENITAL ORGANS.

The speaker referred first to the close relation which is known to exist between the salivary glands and the genital organs of the adult.

He had seen the parotid gland suppurate after a posterior incision of the neck of the uterus. He had had parotid bubo once in one hundred and fifty-three ovariotomies. This occurred in a woman with an immense tumor. At the time of operation she was suffering with septic symptoms following tapping of the cyst. She died on the twenty-second day. He had also seen cases in which there was transferrence to the parotid glands, in which there were no symptoms of septic poisoning. He had seen three such cases. Two followed ovariotomy and one followed oöphorectomy. Not one of the three cases ended fatally, and the speaker regarded the affection as sympathetic rather than symptomatic.

DISCUSSION.

Dr. Sutton reported one case in which this complication appeared after ovariotomy. The patient was almost convalescent, when one gland began to swell. In a week the second gland began to swell. The temperature was one or two degrees above normal. There was some diarrhœa, but no tympany and no soreness over the abdomen. A crop of rose-colored spots appeared over the abdomen and arm. During the third week she became much worse and died. He regarded the case as septicæmic, although others considered it a well-marked case of typhoid.

Dr. Johnson had seen swelling of the parotid glands follow in one case of ovariotomy, ending fatally on the sixth day.

Dr. Mann reported three cases: once after ovariotomy with distinct septic symptoms, ending fatally; once in a case of ovariotomy and hysterectomy, ending in recovery; and once after a penetrating wound of the abdomen, ending in recovery.

Dr. Emmet had seen two cases: once after an operation for lacerated cervix, the patient recovering; once after operation on a small vesico-vaginal fistula, ending fatally.

Dr. Baker reported one case of suppuration of the left parotid gland after Tait's operation. The patient recovered.

Dr. Reamy described two cases. One followed Tait's operation: the patient died. The second was after supra-vaginal hysterectomy: the patient recovered.

Dr. James R. Chadwick read a paper entitled

PERISTALSIS OF THE GENITAL TRACT, AND A NEW THEORY TO EXPLAIN RELAXATION OF THE VAGINAL OUTLET DURING LABOR.

[The scope of this paper is indicated by its title: it cannot be presented in abstract so as to do it justice.—Rep.]

The last paper read was by Theophilus Parvin, M.D., of Philadelphia, and was entitled

FACIAL PARALYSIS IN THE INFANT FROM THE USE OF THE OBSTETRIC FORCEPS.

March 15, 1885, the speaker was called to a case of delayed labor. The first stage had lasted twenty-four hours, and the second stage eight hours. The position was a left occipito-anterior. The only cause of difficulty seemed to be the weak contractions of the uterus. The Davis forceps were therefore applied, and the child was delivered. The following day it was noticed that when the child cried the left side of the face was immovable, the skin smooth, and the eye open. There was scarcely a trace of the pressure of the forceps. The paralysis disappeared in ten days without treatment.

This case was made the basis of a full *résumé* of the literature of the subject.

DISCUSSION.

Dr. Skene referred to the importance of diagnosing facial paralysis the result of injury from facial paralysis the result of apoplexy, for this condition is not infrequent in young infants. As a rule, the diagnosis is not difficult; but when, as in a case which he had recently seen, there was paralysis of the facial nerve from pressure of the forceps associated with paralysis of the arm from injury of the shoulder in hurried delivery, there might be some uncertainty. The presence of ecchymosis would tend to clear up the diagnosis.

The paper was further discussed and cases reported by Drs. Ellwood Wilson, William Goodell, and William L. Richardson.

At the business meeting the Nominating Committee presented the names of the officers for the ensuing year, who were elected:

President.—Thaddeus A. Reamy, M.D., of Cincinnati.

Vice-Presidents.—Theophilus Parvin, M.D., of Philadelphia, and George J. Engelman, M.D., of St. Louis.

Secretary.—Joseph Taber Johnson, M.D., of Washington.

Treasurer.—Matthew D. Mann, M.D., of Buffalo.

Members of Council.—F. P. Foster, M.D., J. C. Reeve, M.D., B. B. Browne, M.D., and R. B. Maury, M.D.

The following new members were elected: Dr. J. B. Hunter, New York; Dr. Charles Jewett, Brooklyn; and Dr. W. H. Parish, Philadelphia.

The next meeting will be held in Baltimore, Maryland, September 21, 22, and 23, 1886.

The Society then adjourned.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, SEPTEMBER 3, 1885.

The President, B. F. BAER, M.D., in the chair.

DR. B. F. BAER read the following report of a case of

OVARIAN CYSTOMA COMPLICATED WITH PERITONITIS AND PHLEGMASIA ALBA DOLENS—DOUBLE OVARIOTOMY.

Mrs. M., æt. 31, has been a widow nine years. She had one child ten years ago, and had enjoyed good health until about three years before I saw her. At that time she observed that her abdomen was increasing in size. This gradually progressed for eighteen months, when she was large enough to attract the attention of her neighbors. After this the growth remained almost stationary, and did not affect her general health until the latter part of March of the present year, when she was suddenly seized with pain in the left iliac region. The pain was acute and radiating in character, extending principally down the anterior portion of the left thigh. She attributed the attack to an unusual exertion. Although she made an effort to continue her vocation (that of seamstress), she was compelled to give up and send for her physician, my friend Dr. John R. Haney, of Camden.

When Dr. Haney first saw her, her abdomen was very tender over its entire surface, purple from congestion, greatly distended, and tympanitic in its upper but dull in its lower portion. She was suffering great pain, and had constant nausea and vomiting; her skin was hot; pulse 120, and temperature 103°. From the history, symptoms, and physical signs elicited, the doctor diagnosticated ovarian cystoma with supervening peritonitis. He administered quinine per rectum and morphine hypodermically, together with counter-irritation over the abdomen. Within a week the patient appeared to be better, when, through the kindness of Dr. Haney, I first saw her. The tympanitis had disappeared, and the pain was not so severe, but the abdomen was still very tender on pressure, especially in the left iliac and right umbilical regions; her features were drawn and flushed and presented an anxious expression; her tongue was dry and heavily coated; pulse quick, and temperature 102°. She lay quietly in the dorsal position, with her thighs flexed. The abdomen was as large as at full term of gestation, and was projecting. It was dull on percussion everywhere except along the line of the colon and in the epigastrium, and there was evident fluctuation. The uterus was retroverted, not freely mobile, and very tender on pressure on the left side. Above and upon it could be felt the lower border of the circumscribed growth which occupied the abdominal cavity. I fully agreed with Dr. Haney's diagnosis of ovarian cyst complicated by peritonitis. As she seemed to be somewhat better, I advised a continuance of the treatment as previously pursued, with the hope of obviating the necessity of ovariotomy during the unfavorable condition in which she then was. The peritonitis continued to improve slowly, but a new trouble presented itself in a very painful swelling of the left lower extremity. This continued until the limb was greatly increased in size. Its temperature was much higher than that of its fellow, which seemed to be in a normal condition. She now required large doses of morphia to relieve her pain, and she was losing flesh and strength. She still had nausea, and took almost no nourishment. Her temperature and pulse had again risen to the highest point noted. Both she and her friends were willing and anxious that we should do something more radical than simply to wait for a more favorable condition for operating, if we deemed it proper. I believed, from the symptoms and physical signs, that the inflammatory action was external to the cyst and not within it, and for that reason decided to wait for a subsidence of the acute symptoms, which I rather confidently expected. At the same time I held myself in readiness to operate at once, should the patient not improve or become worse.

The next day she showed signs of slight improvement. Treatment, both local and general, continued. The acute symptoms gradually subsided to those of a subacute condition. The temperature had decreased to 101°; pulse 100, but weak. She was still

unable to retain food, and was extremely weak. I advised further delay. But she did not improve much after this, her temperature and pulse remaining about the same as noted above. Her stomach had regained its power to a slight degree to retain and digest liquid food.

She had now been confined to her bed more than two months; her left leg was powerless; there had not been the slightest improvement during the two previous weeks. We therefore decided to remove the tumor.

Operation.—June 19, 1885, assisted by Drs. J. R. Haney, W. A. Davis, and H. M. Christian, and in the presence of a section of the class from the Polyclinic, I made an incision three inches in length down to the peritoneum, and then checked the hemorrhage, which was quite free, with clamp-forceps. I next very carefully incised the peritoneum, and found, as I had expected, that it was closely united to the cyst-wall. These adhesions of cyst to peritoneum were universal, and it required careful and patient manipulation to separate them. The parts were exceedingly vascular, and hemorrhage was profuse. After separating it as far as possible, I tapped the cyst and allowed the contents, which were semi-liquid and chocolate-colored, to drain away. I next closed the puncture made by the trocar, and then completed the separation of the cyst from its adhesions and removed it. As there was a very general and free oozing of blood from the broken vessels, I introduced a number of large flat sponges and spread them over the bleeding surface. An assistant now made firm pressure upon the external surface of the abdominal walls, whilst I ligated the pedicle and removed the tumor. The cyst developed in the left ovary, and the pedicle was slender, not unusually vascular, and of good length. The right ovary was diseased, contained a number of small cysts, and was double the normal size. I removed it also. Examination showed that the hemorrhage had almost ceased, but there were still a number of points from which blood flowed. The peritoneum was intensely injected, and I disliked very much to pick up bleeding points, for fear of making the hemorrhage worse. I therefore reapplied a large flat sponge and had firm pressure again made from without, whilst I proceeded to place the sutures for the closure of the incision. I then removed the sponge, and found very little blood upon it. I replaced it by a long narrow strip of sponge, which I allowed to project from the lower angle of the wound, and then again cleansed Douglas's cul-de-sac and other dependent portions of the peritoneal cavity, after which I quickly tied the sutures from above downward, removing the long sponge through the lower angle of the wound before I had encroached so closely upon it as to compress it in its removal. It was only slightly stained. I quickly applied the external dressing, making an unusual amount of pressure by cotton and bandage.

The operation was finished, but the patient bore it badly. Her extremities were cold and purple, her face livid, and pulse very weak. Stimulants hypodermically and the application of external heat, which were begun during the operation, were continued after she was returned to bed. She remained in an almost collapsed state for many hours, but gradually reacted, and the next morning was in a fair condition. Her temperature was lower than it had been for weeks; pulse 112, but weak; stomach quiet; no pain; no tympany. She had taken an occasional small piece of ice, but nothing else except the morphine since the operation.

June 21.—Temperature 102°; pulse 120. Slight pain and tenderness in left iliac region. She had been very weak and faint during the night, for which brandy had been administered in repeated small doses. The swelling and pain in the limb had diminished. She had not vomited since the operation, and felt hungry. Ordered a teaspoonful of milk every second hour.

June 22.—Comfortable and doing well. Temperature 99⅘°; pulse 90, and strong. Slight metrostaxis; passed flatus per rectum. Milk increased to a tablespoonful, and retained.

June 24.—Temperature 99°; pulse 85. General condition greatly improved; no pain; no tympany. Examined wound, and found it united throughout; removed sutures.

June 25.—Doing well, and is bright and cheerful. She took nearly a quart of milk during the last twenty-four hours, and digested it.

June 30.—She has been gradually improving. Temperature normal; pulse 95. Bowels moved to-day. She is taking solid food, and expresses herself as feeling quite well. Limb improving; she can now move it.

July 12.—Sat up to-day for the first time,—the twenty-second after the operation.

August 30.—A note received from Dr. Haney to-day informs me that Mrs. M. is going about attending to some of her duties, but that she has not yet regained her strength fully, and that her limb is still weak.

The recovery of this woman under the forlorn circumstances just narrated is certainly a great triumph for our art, but the case serves a better purpose in forcibly illustrating the danger of deferring operative interference in ovarian cystoma simply because the patient is comfortable and suffering no inconvenience from the presence of the tumor. The subject of an ovarian tumor is in constant danger of injury from slight causes which may produce such changes in the tumor as to render what might have been a simple and safe operation one of extreme hazard. This had been a simple, slow-growing cyst, and had not markedly affected the health during its three years

of existence; yet it suddenly became inflamed, and the patient narrowly escaped death as a result. The case furnishes a strong argument in favor of operation as soon as the disease is diagnosticated. Of course there are qualifications, and each case must be decided on its own merits; but the rule that an ovarian tumor should be removed as soon as it is known to exist, is the only safe one to follow.

As a striking contrast to the case just related, and to show the value of the principle enunciated, I will report the following case of

POLYCYSTIC OVARIAN TUMOR—DOUBLE OVARIOTOMY.

A. R. was sent to me August 5, 1885. She was 19 years of age, single. Puberty was established at sixteen, and she had menstruated regularly until six months previously. She then without cause, so far as she knew, began to flow more freely at her periods, and they continued longer. About the same time she noticed a small lump in the right iliac region. This increased in size so that soon the entire hypogastrium was distended, and when I first saw her she was as large as at the eighth month of gestation. Her face showed marked signs of emaciation and pallor, and the drawn, anxious expression of ovarian cystic disease. She was then having a profuse metrorrhagia every two weeks. She had not suffered any pain, and up to within a few weeks very little inconvenience, except for the frequent metrorrhagia.

During the last month, however, her health had been failing. She had lost flesh, had a weak, languid feeling, and suffered much from the weight of the growth. Physical examination in the dorsal position revealed a projecting, slightly irregular abdomen, larger on the right side, dull on percussion over the entire anterior surface, but resonant along the line of the colon. Palpation showed imperfect fluctuation and several firm, irregular masses within the abdominal cavity. The vagina was virginal, the cervix uteri was pointing forward, the body of the uterus retroverted, the whole organ enlarged and soft. It was only slightly movable independently of the tumor. The sound gave a measurement of three inches.

I diagnosticated polycystic disease of the right ovary, and advised immediate operation. Six days afterwards—on August 11—she entered my private hospital, and on the 13th I operated, with the assistance of Drs. H. M. Christian and J. N. Richards. I made an incision two and a half inches in length, and came upon the surface of the tumor, which presented the white, glistening, nacreous appearance especially common to thick-walled polycysts. Tapped with Hodge's trocar. The contents were so thick that they flowed very slowly, and it was necessary to puncture several smaller cysts, which was done without removing the instrument. Even then the mass did not collapse much, because of a large number of young or child-cysts. After closing the puncture I enlarged the incision to three inches, but I had considerable difficulty in removing the tumor. It was necessary to make firm traction with rotatory movements, whilst Dr. Christian exerted a counter-force and pressure through the abdominal walls. Fully ten minutes were occupied in delivering the tumor after it was tapped, but I was rewarded with an incision that looked so small that it seemed almost incredible that this large mass had passed through it. There had not been a single adhesion, but the pedicle was short, thick, and vascular. I tied it with Tait's Staffordshire knot, cut the tumor away, and dropped the stump. The tissues of the left ovary were found to be entirely disorganized and degenerated into a cyst as large as a walnut. This I also removed. The uterus presented a very vascular appearance, and was somewhat enlarged. After assuring myself that the peritoneal cavity was entirely free from any foreign matter, I closed the incision, dressed the wound, and returned the patient to bed. Temperature normal; pulse 96; no pain; but, as she felt a little sore and restless, one-quarter grain of morphine was given hypodermically; small pieces of ice for thirst.

August 14, 8 A.M.—Temperature 99°; pulse 84. Had passed a good night. At 1 P.M., twenty-six hours after the operation, milk in teaspoonful-doses was allowed; water when she desired it.

August 15.—Metrostaxis began this morning.

August 18.—Union complete; removed sutures.

Her recovery was uninterrupted. She sat up for a few minutes on the eleventh day, and went home—eight miles—in a carriage on the eighteenth day after the operation. To-day she sent a request to be permitted to go out, because she is feeling so well.

Certainly nothing could have been gained by procrastination in this case.

DISCUSSION.

Dr. GOODELL congratulated Dr. Baer on the good results obtained in such a serious case as that first reported. Great care in the asepsis of these cases should be observed. In one of his cases of septicæmia, before the operation, after complete union had been secured, the stitches had been removed, and after the patient was up an abscess was observed forming in the line of union, and was very persistent. Finally, after careful search, a ligature which had been tied around the pedicle of one of the ovarian cysts was found and removed. Subsequently the other appeared, and after its removal the abscess healed.

He did not like to remove the stitches so early as Dr. Baer removed them, and he reminded Dr. Baer of a case in which he had assisted Dr. Goodell. The operation was performed upon December 5: convalescence

was rapid, and the patient was so impatient to be home on Christmas that she could not be restrained, and on the nineteenth day after the operation she took the cars for home. The train was derailed, and the jolting caused the cicatrix to open. The physician who was called in closed it immediately, and the patient recovered. In another case, a cough caused the wound to burst open and reveal the bowels after the stitches had been removed. This patient also recovered. For these reasons he never removed the stitches before the eighth day, and not until the bowels had been opened.

Dr. Goodell inquired of Dr. Baer his method of closing the opening in the cyst after it had been tapped, preparatory to its removal from the abdominal cavity. Does he employ pressure-forceps? What method of dressing the abdominal wound?

Dr. Baer closes the cyst-puncture with Wells's clamp-forceps when the cyst-wall is strong enough. In some cases he stitches up the opening, or ties a string below it when the cyst-walls are loose and soft. He closes the external wound, as he had been taught by Dr. Goodell, with silk sutures, and dresses it with salicylated or absorbent cotton, adhesive strips to hold the cotton in place and take the strain off from the stitches, and over all a bandage. He removes the sutures on the fourth or fifth day, in order to avoid the danger of pus forming in the suture-tracks, as has sometimes occurred when he has allowed them to remain as long as eight days.

UTERINE DILATOR.

Dr. Goodell exhibited his improved *uterine dilator*. He said that the main difficulty in the operation for the rapid dilatation of the cervical canal lay in the liability of the blades of the instrument to slip out. This he had in a great measure overcome by having shallow grooves cut into them. Into these grooves the tissues sank, and the resulting friction kept the instrument in place.

Since he had called the attention of the Society to his instrument, not quite a year ago, he had performed the operation forty-one times for dysmenorrhœa and sterility, making in all two hundred and nine such cases. In not a single instance had dangerous symptoms followed, and the average of success was a very large one. He had become firmly convinced that for dysmenorrhœa and sterility the operation of rapid dilatation of the cervical canal would, except in some very rare cases of stenosis of the os externum, wholly supersede the cutting operation, the use of tents, or the slow dilatation by any means whatever. For by the former not only was the measure of success far greater, but the danger from inflammation was very much less. He dilated the parts from three-quarters of an inch to one inch and a quarter, as measured off by the register in the handles, watching the cervix carefully to see what strain it could bear. His instrument could be opened to the width of one and a half inches, but he resorted to that extreme divergence only when wishing to introduce his finger for diagnostic purposes. This he could not ordinarily do unless the parts were relaxed from hemorrhage. Usually, however, when suspecting the existence of a polypus, he did not find it needful to pass in his finger; for, after a moderate dilatation, he introduced a fenestrated forceps and opened it at hap-hazard. In this manner he has repeatedly caught and twisted off a polypus without knowing it was present, the subsequent removal of the growth through the os uteri being the most difficult part of the operation.

Dr. Baer was strongly impressed, by the case of a lady whom he had delivered to-day, as to the advisability of entirely giving up division of the cervix. A year and a half ago he had slit up the cervix posteriorly, and to-day he felt very anxious during the first stage of labor as to the probability of laceration of the uterus starting from the seat of the former operation. The anterior lip was very long, coming down under the pubis, and the posterior lip could not be felt. The case will be reported fully.

When the uterus contains a polypus, the continued hemorrhages reduce the contractility, and a single dilatation will sometimes enlarge the os sufficiently to admit the finger or forceps; but if the uterus is healthy it contracts immediately after the withdrawal of the dilator. He could not recall an instance of inflammation following rapid dilatation. Sterility of long standing is seldom cured by dilatation or any other means.

Dr. C. M. Wilson had seen recently, in the practice of Dr. Ellwood Wilson, a uterus the cervix of which had been divided bilaterally some years ago. The operation had resulted in the development of the symptoms peculiar to a bad laceration of the cervix, with ectropion. Trachelorrhaphy was performed by Dr. Agnew, with complete relief to the patient. Dr. Wilson mentioned this case to call attention to the change in opinion and practice since Emmet proposed his operation.

Dr. Longaker inquired as to the prevention of slipping of the dilator, and called attention to the original method of pressure over the fundus of the uterus.

Dr. J. G. Allen has performed rapid dilatation over seventy-five times, and has never seen any bad results from the operation. The blades of his instrument diverge as they separate, and there is then no disposition to slip out. The blades are more curved than in Dr. Goodell's instrument; he thinks that an advantage in holding the instrument in place: the handles are turned up so as not to touch the bed or table.

Dr. Goodell prefers the slight curve, so

that in flexion of the uterus he can introduce the dilator with its curve reversed to the bend in the womb, and, by opening the dilator in that position, rectify the flexion of the organ. He prefers parallelism of the blades because the stenosis of the cervix is greatest at the external os, and there is no need for dilatation above the internal os. He considers it dangerous to press the fundus of the uterus down while using the dilator, for fear of wounding or even penetrating the tissues, and he uses a strong tenaculum to hold the organ; but since he had got Mr. Gemrig to roughen the blades by grooves he had not been annoyed by the slipping of the instrument.

Dr. GOODELL exhibited two specimens of

PAROVARIAN CYSTS.

In each case the cyst was so detached from the ovary that the former could have been taken away without injury to the ovary. He was greatly tempted to practise conservative surgery in these cases and leave the ovaries untouched; but, on account of apparently incipient cystic degeneration, they also were included in the ligature and removed. Both these cases were operated on in his private hospital, and both had recovered.

In his experience, the removal of parovarian or of broad-ligament cysts was one of the most successful of operations. Out of a large number which he had performed, he could recall but a single fatal case, and in that the result seemed hardly due to the operation. The lady lived in a distant city, and he did not see her after the operation, which was a very easy one. At the end of a week the bowels were moved, the stitches removed, and everything gave promise of an unusually prompt convalescence. On the twelfth day, however, she was seized with uncontrollable vomiting, and she died on the seventeenth day. Six months previously she had had an analogous attack of vomiting, from which she barely escaped with her life. Thus far this year he had had eighteen ovariotomies, and this was the only fatal case among them.

Dr. MONTGOMERY wished to ascertain the opinion of the Society as to the advisability of removing the second ovary when, in an operation for the removal of an ovarian cyst, the other ovary was found to be slightly diseased. In his first ovariotomy, performed in 1879, the second ovary was found to contain numerous small cysts. It was not removed, and the patient has since been twice pregnant, and there has been no appearance of another tumor, nor any symptoms referable to the remaining ovary. If the climacteric has been passed, there would be no question about it.

Dr. BAER inquired if tapping ever cured parovarian cysts. It was formerly reported as a means of cure. Do they always return after tapping? Would Dr. Goodell recommend tapping in undoubted parovarian cyst? He himself felt strongly inclined towards abdominal section in all cases. He thinks the second ovary should be removed when it is not healthy, as the idea of a second operation is very depressing to a patient.

Dr. MONTGOMERY knew of one instance of parovarian cyst which had been tapped and had refilled seven times. It was finally removed by him by peeling out the cyst, as, on opening the abdomen, he found the tumor universally adherent. Only one ligature was required,—viz., on the stump of an enlarged ovary which bulged prominently into the cyst-cavity.

Dr. J. G. ALLEN considered that as an ovary somewhat diseased may give rise to a pregnancy, it should be left. We know too little about the probability of the development of such small cysts into large ones. Until we have certain data on the subject, it must be considered a case of want of information and knowledge.

Dr. PARISH was in accord with Dr. Allen as to the want of knowledge. He has seen diseased ovaries containing numerous small cysts in many autopsies, and there had been no symptoms during life to excite a suspicion of their existence. The existence of minute cysts cannot be considered as proving any liability to the production of large ones. If the second ovary contained a cyst as large as a partridge's egg, he would remove it; but if numerous cysts as small as split peas were present, he would not. The possibility of conception should be considered as well as that of a cyst.

Dr. GOODELL acknowledged the truth of the points made by Drs. Allen and Parish, and he believed that he had repeatedly removed the second ovary unnecessarily. Yet the history of his own ovariotomies shows a return of the disease in the remaining ovary in about two per cent., and he thought he erred on the safe and right side. The social conditions of the patient would always have a great weight with him. If an heir were wanted or the patient were young, he would leave a suspicious-looking ovary or try to remove the diseased portion of it. But in the majority of his cases where there was any doubt he removed the ovary. Of course, under such a rule he must remove ovaries which might never give any trouble in the future. But the mental agony of women when informed that the operation must be performed a second time upon them, and, on the other hand, the great joy and satisfaction of patients when assured, after the close of an operation, that both ovaries had been removed, have determined him that, other things being equal, it is better to remove the second ovary.

As to the cure of parovarian cysts by tapping, his own experience is not sufficient yet to decide absolutely. He would advise the

radical operation; but if the patient, after understanding the liability of return, wished it, he would tap, as there was but little danger from tapping such cysts. A patient was tapped by Dr. Atlee some twenty years ago; five years afterwards the cyst filled, and was tapped by Dr. Goodell. It then partly refilled, and so remained for a long while; the fluid then was gradually absorbed, and never returned. He has had, besides this one, two cases which he tapped, one five years ago and the other three years ago, and there has been no return whatever of the fluid. On the other hand, he has had two or three cases in which the cyst burst spontaneously several times and yet refilled invariably. The rupture was followed immediately by some collapse and pain, and later by an excessive secretion of urine with complete subsidence of the tumor. He had also heard of several cases of rupture, but, as far as he has learned the history of such cases, the cyst has always returned. The reports of the cure of ovarian cysts by tapping and injection of tincture of iodine must be true only of parovarian cysts.

Dr. HARRIS knew of a case of parovarian cyst in which fourteen years had elapsed between the tapping and the subsequent refilling.

(To be continued.)

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, APRIL 23, 1885.

The President, E. O. SHAKESPEARE, M.D., in the chair.

NOTES ON THE MORBID ANATOMY OF PNEUMONIA.

DR. OSLER read a paper summarizing his experience while Pathologist at the Montreal General Hospital. Of one hundred and five autopsies in cases of lobar pneumonia of which notes were available, five were discarded for various reasons. The mortality at the hospital is high, on account of the large percentage of grave cases which are admitted, very many subjects being debilitated and dissipated.

Of the one hundred cases, seventy were males and thirty females. Of ninety-four instances in which the age was given, there were eleven cases under twenty years, twelve between the twentieth and thirtieth, eighteen between the thirtieth and fortieth, twenty between the fortieth and fiftieth, twelve between the fiftieth and sixtieth years, and twenty cases over sixty. In fifty-one cases the right lung was affected, in thirty-two the left, in seventeen both. Other details were given of the various lobes affected. The heaviest lung weighed was two thousand three hundred and three grammes, and in eight instances the affected organ weighed over two thousand grammes. In about fifty per cent. of the cases there was red hepatization, in thirty per cent. mixed red and gray, and in about twenty per cent. gray hepatization. The condition of the pleural air-passages, bronchial glands, and unaffected portions of the lung-tissue were described. Among the terminations there were four instances of abscess formation, three cases of gangrene, and one in which there was a process of fibroid induration beginning in the lung. This case was a man aged 55, admitted with pneumonia of the right lung five days after the initial chill. Resolution did not occur, and he died in the fifth week. Post mortem, the right lung was found solid, grayish in color, and in many areas the tissues had a smooth, homogeneous, translucent aspect, and in these a fibroid change was going on; the alveolar walls were thickened, and the fibrinous plugs in the air-cells seemed undergoing transformation into connective tissue. (A slide was shown illustrating this.) There were no caseous portions, and no tubercles.

As to the other organs, the frequency with which large, firm clots were found in the heart was specially dwelt upon. In only thirty-five instances was the spleen much enlarged. In one it weighed six hundred and seventy grammes. In twenty-five per cent. there were marked fibroid changes in the kidneys. Of the complications, there were four cases of pericarditis and sixteen cases of endocarditis. In eight instances the meninges of the brain were inflamed, in five of them associated with ulcerative endocarditis. In five instances there was acute croupous or membranous colitis, and in one instance croupous gastritis.

Dr. TYSON, in the discussion of Prof. Osler's paper, said that he had been rather incredulous of the termination of croupous pneumonia in fibroid induration, but the specimen exhibited by Dr. Osler demonstrates conclusively that such a condition exists. The facts presented in the paper are such as are not generally collated. Collective reports of autopsies in cases of particular forms of disease would be of great value in the study of pathology.

Dr. FORMAD asked Dr. Osler why his was not a case of acute phthisis. Croupous pneumonia is a very common accident in acute phthisis. It is croupous pneumonia which causes death, which is well shown by recent investigations of Mercur, of the University of Pennsylvania. Dr. Formad did not believe that croupous pneumonia can last five weeks.

Dr. SHAKESPEARE said that the remarks of Dr. Osler about the frequent existence of very firm clots in the right heart, extending into the ventricles, can be corroborated by any one who makes autopsies of cases of pneumonia at hospitals. He had seen them in cases of phthisis

quite as extensive and firm, reaching into the vessel going to the affected part of the lung. It is interesting to note the systemic involvement of these cases of croupous pneumonia, and the affection of internal organs as well as lungs in the process which has been regarded as a local disease. We have to do with a general, wide-reaching affection rather than local inflammation. The opinion was advanced by Dr. Osler that the exudate in the air-cells organized, that the process in the organization of the croupous exudate is similar to that in the clot in arteries after ligation, and that comparison was the point which Dr. Shakespeare wanted to bring out. Dr. Shakespeare said that he did not believe that a blood-clot in a vessel ever organizes, and his opinion is based on facts detailed in an investigation which he has published on the healing of arteries after ligature. The vessel healed not by the agency of the white cells caught in the meshes of the reticulum, but by proliferation of the endothelium of the tunica intima and subjacent connective-tissue cells. He thought there was reason to believe that there is in this process in the lungs an analogue of the process after ligature. We have to do with an outgrowth of the inter-alveolar walls. The ground which Dr. Shakespeare takes is purely that of analogy to the process in a blood-clot in a ligatured artery.

Dr. Osler, in closing the discussion, said that it was well known that a croupous pneumonia might persist five or six weeks, or even longer, before resolution took place. It was difficult for any one who had not had the experience to realize the anxiety which such a case would cause. He had reported two such cases of delayed resolution, one in the fourth week and one in the eighth, both with perfect recovery. He was quite aware of the difficulty in distinguishing certain cases of acute phthisis from pneumonia, and had seen a case with Dr. Ross in which the diagnosis was for some time in doubt; but in the case in question the person had been under observation from the outset, and the symptoms were those of ordinary pneumonia. Post mortem there were no caseous masses, no miliary tubercles; only the condition already described. The termination in fibroid induration, though rare, was frequently well recognized. In Cornil and Ranvier's Manual, as well as in Green's Pathology, was a figure which might have been taken from the slide under the microscope.

Dr. M. H. Fussell, of Manayunk, presented specimens from a case of

PRIMARY TUBERCULOSIS OF THE KIDNEYS.

The reporter never saw the subject alive from whom the specimens were removed, having performed the post-mortem examination for a friend.

Case of Edward B., æt. 40, single, by trade a paper-maker. In following his calling he was forced to stand in a dust-loaded atmosphere from morning until night. He worked at this trade from boyhood steadily, with the exception of four years during the late war. His grandfather died of bladder-trouble; his father died of apoplexy; his mother, brothers, and sisters are all living and healthy. He was always a robust man; his weight was one hundred and seventy pounds, and he never had any serious illness; he had gonorrhœa during the war. Four years ago, while in camp, he made a misstep and fell. The next morning he passed much blood in his urine. Previous to this he was perfectly well. From this time until death he was troubled with slight pain in his loins and with frequent micturition; his urine was sometimes bloody, sometimes milky. The patient's bladder finally became incontinent, and he was forced to wear a urinal.

The patient's general strength did not seem to suffer until the past six months, when he began to lose flesh and strength, and at death he was much emaciated. He had never had any cough or diarrhœa. Two weeks before death he began to vomit: this increased in frequency until he was unable to retain anything on his stomach. Just before death breathing was rapid and full. The patient was very restless, vomited, and passed urine freely. The pupils were dilated.

Dr. Fussell examined the urine several times. The specific gravity ranged from 1.002 to 1.010. Large amounts were passed. Albumen was present. The microscope showed pus, blood, and granular epithelium. Many of the cells were irregular in shape, the pyramidal form predominating. No casts were found at any time. Unfortunately, a critical physical examination of the patient was never made. At different times surgeons had sounded him for stone and had failed to find any.

Post-Mortem.—Nothing especial noted on the exterior of the body. *Thorax:* Heart about normal in size; the muscle looks normal, and contains a large amount of fluid blood and currant-jelly clots; a small decolorized clot on the left side; valves normal.

Lungs: Both pleural cavities obliterated; the pleuritic adhesions were tough, the lungs being with difficulty torn from the cavity; in places the pleura was much thickened; the surface of both lungs was studded with miliary tubercles; on section, the lung-substance was crepitant and studded with myriads of miliary tubercles; no caseous masses nor cavities were found in either lung; the bronchial glands were enlarged, not caseous.

Abdomen: Viscera in normal position; peritoneum free from tubercles and of a healthy look.

Liver of normal size and color; over the surface a few stellate cicatrices noted, but no tubercles seen on the surface, nor on section of the organ; the bile-ducts free.

The stomach contained greenish-black fluid, the mucous membrane of a greenish color corresponding to the contained fluid; the rugæ were much enlarged, especially at the cardiac end; near the pylorus was a small injected spot.

Kidneys: The right measures six inches in length and three in width, and is of a reddish hue; the surface is studded with tubercles; on stripping off the capsules, the larger of these remain with the kidney-structure, while some of the smaller ones are torn off; on section, the cortical substance is seen to have a thickness of about one-third of an inch; numerous foci of softening are seen, of the size of a nickel five-cent piece; there are very many smaller ones, situated mostly in the pyramids; numerous miliary tubercles throughout the substance of the kidney; the foci of softening are evidently due to breaking down of the tubercles; the ureter is dilated, measuring half an inch across in some portions; the mucous membrane is ulcerated; the pelvis of the kidney is not dilated, and shows miliary tubercles.

The left kidney is large, and is converted into five or six cysts; there is but little kidney-substance remaining; the surface of the kidney is studded with a few tubercles; the cysts are lined by a thick leathery membrane, which can be stripped from the kidney-substance; on puncturing the cysts, a perfectly clear serous fluid at first escaped, soon followed by a milky substance containing some cheesy masses; the pelvis is smaller than usual, the ureter entirely occluded.

The supra-renal capsule has undergone degeneration, is of a uniform yellowish-white color, and presents tubercles.

The bladder was slightly contracted, the mucous membrane ulcerated, the muscular coat being exposed; the vesical trigone of a vivid red color and studded with miliary tubercles.

The intestines were found to be normal; no enlargement of lymphatic elements; the mesenteric glands were slightly enlarged; the prostate gland and spleen were not examined.

Prof. William Osler kindly made sections of the kidney and supra-renal capsule, and the reporter is indebted to him for the following report:

First. Extensive, wide-spread, small-celled infiltrations between tubules and Malpighian tufts.

Second. Distinct miliary tubercles, with centrally-placed giant-cells.

Third. Areas of softening and disintegration. Tubercle-bacilli carefully sought for, but only two undoubted specimens found.

Supra-renal capsule showed miliary tubercle with centrally-placed giant-cells.

Dr. FORMAD referred to a similar specimen which had been exhibited by Prof. Tyson at a former meeting of the Society.

Dr. OSLER remarked that Dr. Fussell's case corresponded in all essentials to what we know as tubercular nephritis. The bacilli, however, were scarce and difficult to find. Since the report of Dr. Tyson's case a few weeks ago, he had had occasion to look over the notes of several cases, and found that they formed a complete series, from cases of unilateral disease to instances with tuberculosis of the entire urinary tract and general infection. The condition was not infrequently met with accidentally in persons dead of other affections.

TUBERCLE-BACILLI IN THE URINE.

Dr. OSLER showed a slide of pus from the urine in another case of tuberculous kidney, with the tubercle-bacilli stained.

The President, Dr. SHAKESPEARE, reported a case of

INTESTINAL STRICTURE.

The patient was admitted to the Philadelphia Hospital one week previous to her death, under the care of Dr. Evans, the house-physician. She had obstinate constipation, followed by stercoraceous vomiting. She suffered acutely, lapsed into an unconscious state, and died, all treatment proving ineffectual.

At the autopsy the thoracic organs were found apparently normal. In the right iliac fossa a lobulated tumor was apparent on opening the abdominal cavity. The colon was distended with gas in the transverse portion, and in the descending portion was narrow. The ascending and transverse portions had hardened fæces. There was a double twist of the intestine and two strictures,—one in the ileum, two inches above the ileo-cæcal valve, and one two inches below the valve. They would not admit the finger. There was a ring of hardened tissue in each stricture. There was congestion of the mucous membrane in the small intestine, and adhesion of the first part of the ascending colon on its under surface to the abdominal parietes. The kidneys were normal. A large tumor of the right ovary was also present, attached to the uterus.

Dr. FORMAD, who made the autopsy, remarked that acute peritonitis had in this case become chronic, and that it was the contraction which made the strictures. The cause was probably the abdominal tumor. He was not aware that there was a case on record where a tumor produced stricture. The constriction was due to outside pressure.

NITRO-GLYCERIN is highly praised by Rossbach (*Berl. Klin. Woch.*) as a remedy for contracted kidney. It is usually given in doses of two to three drops of a one-per-cent. solution in alcohol.

REVIEWS AND BOOK NOTICES.

How to Drain a House: Practical Information for Householders. By George E. Waring, Jr., M.Inst.C.E., Consulting Engineer for Sanitary Drainage, Newport, Rhode Island. New York, Henry Holt & Co., 1885. 12mo, cloth, pp. 222. Price, $1.25.

In the growing interest shown by the community in hygienic matters, and the increasing intelligence as to the rational causes of health and disease, there is promise of prospective benefit to the medical profession; for the better the public can be brought to understand problems of health and disease, the more discriminating will it be as regards the intelligence and skill of its medical attendants. Imposture thrives upon ignorance; and it is therefore to the interest of the medical profession to enlighten the people, in order that they may be more exacting in their requirements. The reaction will certainly advance the standard of medical practice.

Colonel Waring's book can be read with interest and profit by all who are interested in domestic hygiene, and it will serve to strengthen the arguments of the medical attendant in cases of needed improvements in houses where typhoid fever or diphtheria exists, or where it is only threatened.

The Formation of Poisons by Micro-Organisms. A Biological Study of the Theory of Germ-Disease. By G. V. Black, M.D., D.D.S. Philadelphia, P. Blakiston, Son & Co., 1884. Pp. 178.

This is a clear, concise, and judicious exposition of the present status of the germ-theory of disease, arranged in the form of lectures, which allow of a more popular and readable method than the ordinary style of the scientific treatise. In an appendix the application of the germ-theory to dental caries is discussed.

A Text-Book of Physiology. By M. Foster, M.A., M.D., F.R.S. Third American from the Fourth and Revised English Edition. With Extensive Notes and Additions by Edward T. Reichert, M.D. With Two Hundred and Seventy-One Illustrations. Philadelphia, Lea Brothers & Co., 1885. Sheep, 12mo, pp. 911.

Foster's Physiology does not need to be introduced to our readers. Its arrangement is very good. Commencing with the study of plasma and the chemistry and physiology of the blood, the contractile tissues, the nervous tissues, and the vascular mechanism are considered in book first; book second takes up the functions of special organs and apparatus; book third, the central nervous system, its instruments and functions, concluding with special muscular mechanisms; while book fourth is devoted to the tissues and mechanisms of reproduction. The work is clearly written, and the illustrations are good. The additions made by Dr. Reichert have considerably enhanced the value of a work which has a recognized position as a text-book having special advantages for students.

A Complete Pronouncing Medical Dictionary, embracing the Terminology of Medicine and the Kindred Sciences, with their Signification, Etymology, and Pronunciation. With an Appendix. By Joseph Thomas, M.D., LL.D. On the Basis of Thomas's Comprehensive Pronouncing Medical Dictionary. Philadelphia, J. B. Lippincott Co., 1886. 8vo, cloth, pp. 844.

This is a handsomely-printed volume of eight hundred and forty-four double-column pages, forming a valuable work of reference. In examining the work it is evident that much learning and labor have been expended upon it in preparing concise definitions, and its etymologies are unusually full. It is planned to include the technology of the kindred sciences, but especial attention has been given to medicine. Its appendices are articles upon Latin phrases and on writing prescriptions, with tables of doses, orders and families of living mammalia, chemical symbols, and metric weights and measures.

NEW REMEDIES AND CLINICAL NOTES.

Treatment of Syphilis by Liebreich's Method.—It is now some time since the employment of subcutaneous injection of hydrargyrum formamidatum was recommended in the treatment of syphilis. The interval has not been misspent by Dr. Carl Kopp, who has brought together the results of his experience in the *Vierteljahr. für Dermatologie und Syphilis*. Altogether three thousand injections were made on one hundred and twenty-six cases, giving an average of twenty-five injections per case. Sixty-five cases were males, and sixty-one females. Fifty-three times the disease was treated while in its primary form. The secondary stages were treated seventy-one times. Only two cases belonged to the tertiary period. The symptoms disappeared under the treatment in ninety-two cases. Thirteen times the injections had to be discontinued on account of untoward effects. In spite of prolonged treatment, eleven cases failed to be benefited by this method. Ten cases were doing well under the treatment, but this was allowed to lapse from some cause or other. Tenderness about the seat of injection was noted altogether sixty-five times; thirty-four times this

subsided in an hour, and in the remainder the tenderness lasted from two to twenty-four hours. Forty-one times an induration developed at the point of puncture. An abscess formed once, in a woman. Salivation and stomatitis were recorded twelve times, eight times in men. The injections were continued for a long period in thirty-nine cases, without any unpleasant after-effects. Universal erythema in a woman, eczema of both lower extremities in a man, and parenchymatous nephritis in a woman were the complications observed during the treatment; but it would be difficult to say what share the injections had in their production.

We append some of the conclusions formulated by Dr. Kopp. Liebreich's preparation is decidedly useful in certain of the milder forms of primary lues, as also for many slight secondaries. The formamide should not be employed in severe cases where there are large papules or thick infiltrations: inunction is still the best method of treating these cases. The tertiary forms are likewise not to be treated by the formamide. Relapses are by no means prevented by Liebreich's method; on the contrary, they appear to be extraordinarily common after this treatment. —*Lancet.*

The Use of Antimonials in Pneumonia and Inflammation.—D. Leith Napier, M.D. (*Practitioner* for September), states that while children do not bear the antimonials as well as adults, the following "mistura scillæsalina" has proved of great utility (sometimes combined with a suitable dose of belladonna or hyoscyamus) in the febrile catarrhal condition attending dentition:

Saline Mixture.

℞ Liq. antimonii tart.,
Spts. ætheris nitrosi, āā fʒiij;
Liq. ammon. acet., fʒij;
Aquam ad fʒviij. M.
Fiat mistura.

Squill Mixture.

℞ Vin. ipecac.,
Vin. antimonii, āā fʒij;
Syr. scillæ, fʒij;
Aquam ad fʒviij. M.
Fiat mistura.

These mixtures may be given alone, the first being more generally employed. In some cases the squill mixture is given alone, as in the latter stages of pneumonia; but, as a rule, equal parts of each were used.

The benefits of antimonials are more evident in pneumonia than in other inflammations; but, while Dr. Nias (*Practitioner* for August) follows Trousseau in giving comparatively large doses in the stage of engorgement (not hepatization), Dr. Napier treats the first stages with salicylic acid, antipyrine, or quinine, reserving the antimony for the stage of resolution, except in cases marked by low stamina and great debility.

Treatment of Vomiting of Pregnancy.—Two causes are cited by Dr. Morival (*Thèse de Paris*, 1884) to explain the persistent vomiting in some cases of pregnancy: neuræsthenic influence and organic lesions. In treatment, the first effort should be directed towards the discovery of organic lesions, because they may often be relieved with facility. The most frequent are uterine deviations, ulcerations or stenosis of the uterine neck, and perhaps the abnormal adhesions of the membranes. For ulcerations a ten-per-cent. solution of nitrate of silver may be used with advantage. With regard to versions, their reduction should be effected in the horizontal posture, with the hips higher than the head; this postural treatment should be maintained for several weeks. If no apparent lesions are found, resource can be had to medical means, at first anti-nervous,—potassium bromide, belladonna, morphine, applications of ice or of ether spray; then inhalations of oxygen might be tried, or galvanism with a continuous descending current. In all cases stimulants and nutrient enemata should be employed. Should these means fail, digital dilatation by Copeman's method may be resorted to; and, as a last resort, premature delivery should be practised if all other means fail to check the vomiting.—*Bull. Gén. de Thérapeutique*, August 30. (Probably the best remedy for persistent vomiting is cocaine, as suggested by Dr. Bauduy, *New York Medical Journal*, September 26, 1885.)

Concentrated Solutions of Saline Cathartics in Dropsy.—Dr. Matthew Hay, of Edinburgh (who has accepted a chair at Johns Hopkins University), presented a novel method for the treatment of serous effusions in the *Lancet* (April, 1883), the good results of which have been recently reaffirmed by Dr. W. G. Eggleston (*Jour. Amer. Med. Assoc.*, March, 1885). In cardiac dropsy, or pleural or abdominal effusion, abstinence from water and liquid food is enjoined for one day, and on the following morning a comparatively large dose (three ounces) of magnesium sulphate dissolved in two tablespoonfuls of hot water is to be administered. The results which have been reported have been surprising, especially where the saline is repeated on the second morning. Large watery evacuations are obtained, and the effect may be enhanced by the subsequent use of jaborandi (ext. fld. twenty drops), to act upon the skin. This method of treatment deserves further trial by the profession, not forgetting, however, that in children or persons subject to bowel-disorder a serious entero-colitis might be developed. Christison reported a case of a boy who took two ounces

of Epsom salt and died with symptoms of gastro-enteritis without purgation. The hypodermic injection of solution of magnesium sulphate has been advocated in cases of dropsy.

Hydrobromate of Hyoscine.—Prof. H. C. Wood, in the *Therapeutic Gazette* for September, publishes an additional note upon his experience with the hydrobromate of hyoscine. The dose for an adult he places at one-eightieth of a grain. In spermatorrhœa he believes it to have a specific field of usefulness: thus, in a case in which the discharges were three a week, they were completely arrested by a dose of one-seventy-fifth of a grain at bedtime each night. The effects of the drug do not seem to be very lasting, but they are quite evident during its administration. It was employed in the penitentiary by Dr. Robinson, who reported that its results were surprisingly good. In a case of a woman with eroto-mania its influence was also decidedly beneficial. As a hypnotic it is useful where sleep is prevented by too great cerebral activity, by a succession of thoughts, or where sleep is disturbed by urgent dreams. In intense fever with delirium the hyoscine has seemed to control this symptom. Used hypodermically, in one case it seemed to produce a paralyzing effect upon the pneumogastric nerves; the patient, a woman, had an attack of suffocation, apparently paralytic and laryngeal. The dyspnœa of a child suffering with anginose scarlet fever was much increased after taking the drug, and in the course of an hour or two death resulted, whether from the use of the drug or not is uncertain; but these two cases are sufficient to arouse suspicion.

Ammonium Carbonate in Scarlet Fever.—Dr. A. W. Jackson, of Brooklyn, calls attention to the treatment of scarlatina first brought prominently into notice by Dr. Peart, of England. This consists in the administration of from three to seven grains of carbonate of ammonia every hour for the first day, and then at longer intervals. Purgatives are to be avoided during the early stages of the disease. The writer states that he has had occasion to test this mode of treatment, and can endorse it heartily. In addition, he employs the fluid extract of eucalyptus internally and as a gargle. When there is much exudation, a mixture of carbolic acid and iodine in glycerin is painted over the parts. In too rapid recession of the rash, Dr. Jackson applies cloths dipped in thick mustard-water, or wraps the child in blankets wrung out in hot water.—*Medical Record.*

Naphthaline in Chronic Intestinal Catarrh.—Dr. P. Selfverskiöld, of Sweden, has employed naphthaline in intestinal catarrh with advantage. To children it may be given in mucilage, and to adults in capsules with a drop or two of ethereal solution of bergamot. The drug should be purified by washing with alcohol and resublimation; of it one or two drachms are given in divided doses during the day. The dose recommended by Pauli was: for children under one year of age, one grain and a half daily; for those of five years, four to five grains. In chronic cases of intestinal catarrh this remedy has proved to be advantageous.—*Lancet.*

Quillaia Saponaria has been recommended as a substitute for senega by Dr. Kobert (*Centralblatt für Klinische Medizin*). The glucosides contained in senega are found in almost the same proportions in quillaia, which is cheaper, easier to take, and is less expensive than senega. It is best given in a decoction (quillaia, 5 parts; water, 200), of which the usual adult dose is a tablespoonful. Inflammatory conditions of the alimentary canal and gastric ulcer are contraindications against the use of the drug.—*Therap. Gaz.*

Permanganate of Potassium in Amenorrhœa has found a recent advocate in Dr. E. J. Doering, of Chicago. It is administered in capsules midway between meals, and is to be followed by large draughts of some pure mineral water, like Silurian. It is required to be continued for two weeks in doses of from two to four grains several times daily.—*Med. Journ. and Examiner.*

Administration of Paraldehyde.—

℞ Pulv. tragacanth. comp. (Br.), gr. xx;
Syr. aurantii, ʒiv;
Paraldehydis, ʒj;
Sp. chloroformis, ♏xv;
Aquæ, q. s. ad ʒiij. M.

To be given at bedtime in a single dose.—William Craig, M.D., in *Brit. Med. Jour.*

MISCELLANY.

Changes of Address.—Roberts Bartholow, M.D., has removed his residence and office to 1525–27 Locust Street.

Theophilus Parvin, M.D., has removed to 1718 Walnut Street.

Charles K. Mills, M.D., has removed to 1909 Chestnut Street.

B. F. Baer, M.D., has removed to 2010 Chestnut Street.

J. M. Holland, M.D., has taken an office at 1914 Rittenhouse Square.

The Address Introductory to the One Hundred and Twentieth Course of Lectures in the Medical Department of the University of Pennsylvania was delivered by Prof. William Osler, M.D., on Thursday, October 1.

The Introductory to the Sixty-first Annual Course of Lectures at the Jefferson College was delivered September 30, at the Hospital of the College, by Prof. J. W. Holland, M.D.

Liebig's Beef Tonic.—Dr. W. F. Steuart, of the Marine Hospital, Baltimore, Maryland, pronounces "Colden's Liquid Beef Tonic" an excellent invigorator of the system.

NOTES AND QUERIES.

MR. EDITOR,—I trust it will not be considered indelicate if I make an editorial on "The Attitude of the Medical Profession towards Criminals," published in the *Medical Times*, August 22, the subject of some comments. First, I may say that I heartily approve the sentiments there expressed, and, inasmuch as it amounts to a general invitation to the profession for an expression of opinion on "the nature of punishment, its effects upon the individual, and its practicability," a few reflections may not appear out of place.

In New York, as in all large cities, there are each day a number of persons committed to prison for a term varying from a few days to a few months, because of minor offences against the law. Now, the treatment of this class of prisoners must necessarily differ somewhat from that of criminals consigned to the penitentiary for one or more years. In the case of the latter the term of imprisonment is sufficiently long to admit of a course of discipline which may be considered as not only punitory to the individual, but also as tending to improve his moral and perhaps physical state. His imprisonment, in other words, can be made a graded school of moral and physical training. The great length of time for which the person is to be confined, aside from any other consideration, would necessarily make him feel that he was undergoing a punishment. No tramp, however low his condition, it may be safe to say, would voluntarily commit a crime with the hope of finding in the walls of such a prison a comfortable home, sheltered from the storms of an inclement season.

My impression is that the greatest evil arising from modern sentimental prison reform is the influence which it has upon persons who contemplate doing acts for which they will be liable to be imprisoned for only a few days or months. Many of this class of persons are lazy, filthy, habitually addicted to drink and bad food, and perhaps to sleeping out of doors. Their self-respect is not so great as to make them feel ashamed of being sent to "the island" (a term synonymous in New York with the prison). Now, what sort of punishment would it be for one of these persons—who had, for instance, without provocation insulted a lady and broken a gentleman's nose—to be taken out of the cold and dirty streets and sent to a prison for a few weeks or months, where he would be accommodated with a warm cell, a decent bed, perhaps provided with a clean suit of clothes, given good food and medical care, and allowed to lie in idleness, or at least not compelled to do a sufficient amount of labor to pay for half the expense the city had incurred in feeding and sheltering him in his new home? There are two important facts to be taken into consideration in dealing with violators of the law, aside from but intimately connected with the protection of the state,—namely, the treatment of the transgressor in a manner to make him feel that he is being punished, while at the same time improving him morally. The mere fact of his being a transgressor of the law shows that he is morally defective. Now, it is just the compelling him to do such things or to undergo such restrictions as will develop this that will be regarded by him as the greatest punishment. Now, cleanliness and a proper supply of wholesome food and exercise are not opposed to morality, but the contrary. The violator of the law should be compelled to keep himself clean, to earn his own food, and to obtain exercise by doing such work as may be assigned to him to do. What greater punishment to the law-breaker, consistent with Christian doctrine, than to take from him his liberty, make him live soberly, and compel him to labor? The tramp dislikes nothing more than labor and restraint. The petty thief, as well as the bank-robber, has obtained this title because of a dislike for honest labor. The woman-beater would rather do anything else than to embrace the whipping-post or be confined and compelled to break stone or delve in the earth. Honest industry and living without many of the luxuries of life are generally distasteful to all habitual violators of law, especially so when observed under compulsion. Yet this is the lot to which the majority of men are of necessity subjected,—men who really constitute the power of the state. Why, then, should evil-doers, who are practically a nuisance to the community, be exempted from that to which Providence has called the best of mankind, and which to this evil class is the greatest of punishments while it is at the same time of benefit to the state? The addition of filth and unwholesome surroundings in prison-life would be a punishment only to the decent man who had accidentally got himself into the clutches of the law, and for whom restraint and hard physical labor would be sufficient to bring about repentance. For the habitual violator of social order and decency such surroundings would simply be a continuation of that to which he was habituated. But if he were himself compelled to do his own cleaning in addition to his other daily labors, it would be to him a punishment, while at the same time to his own advantage and that of his fellow-prisoners. These persons sent to prison for only a short time could not of course be expected to learn a trade, as some do who are sentenced for years. Certainly this would not be as great a punishment as if they were compelled to do farm or agricultural work. If there were no opportunity to labor at farm-work, there could always be an opportunity to break stone or work on public improvements. No man should be allowed to board and obtain superior diet, or shirk his duties, by paying the warden an extra fee. Ferdinand Ward, who it is claimed nearly ruined the Grant family, it is said is enabled to live in jail like a prince by paying the warden seventy-five dollars a week from his stolen money.

It is true that some opposition has been manifested towards prison-labor on the supposition that it depreciates the value of work done by honest citizens. But this is the view of the politician and individual, not of the statesman and nation. It could not be expected if I were a shoemaker, and should go to a town where there was but one other shoemaker, that he would welcome me as a rival; but the citizens in general would be glad to have me settle among them and ply my trade, especially so if in not plying my trade they should be compelled to support me gratuitously out of their own daily earnings. The same should be true of prison-labor. If prisoners do not work, then we must take bread from the mouths of our children and give them to eat without being recompensed. But he who produces more than he consumes becomes the servant of the people, or makes the state his debtor. If the tramp does not dread such prison-life, but prefers to be "sent up" for ten days to sleeping out in the cold, the public will not object, so long as they know that while there he is earning them bread and butter and giving them a day of rest.

Thus far only a portion of the questions suggested in the editorial referred to have been touched upon. Perhaps some time in the future I will take the liberty of expressing some ideas regarding the ability of specialists to declare upon the sanity or insanity, responsibility or irresponsibility, of criminals. Space will not admit of it at present.

Truly yours,

R. C. SHULTZ.

NEW YORK, September 3, 1885.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 13, 1885, *TO SEPTEMBER* 26, 1885.

COLONEL JOHN CAMPBELL, SURGEON.—Retired from active service September 16, 1885. S. O. 212, A. G. O., September 16, 1885.

PROMOTIONS.

LIEUTENANT-COLONEL T. A. MCPARLIN, ASSISTANT MEDICAL PURVEYOR.—To be Surgeon, with rank of Colonel, to date from September 16, 1885.

MAJOR B. J. D. IRWIN, SURGEON.—To be Assistant Medical Purveyor, with rank of Lieutenant Colonel, to date from September 16, 1885.

CAPTAIN B. F. POPE, ASSISTANT-SURGEON.—To be Surgeon, with rank of Major, to date from September 16, 1885.

APPOINTMENT.

EDWARD R. MORRIS.—To be Assistant-Surgeon, with rank of First-Lieutenant, to date from September 17, 1885.

CAPTAIN F. C. AINSWORTH, ASSISTANT-SURGEON.—From Department of Texas to New York City, for duty as member of the Army Medical Examining Board. S. O. 214, A. G. O., September 18, 1885.

CAPTAIN G. W. ADAIR, ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply for one month's extension. S. O. 104, Department of Dakota, September 18, 1885.

CAPTAIN WILLIAM C. SHANNON, ASSISTANT-SURGEON.—Granted leave of absence for four months, to take effect about October 1. S. O. 215, A. G. O., September 19, 1885.

FIRST-LIEUTENANT GEORGE E. BUSHNELL, ASSISTANT-SURGEON.—Ordered from Department of Dakota to Department of the East. S. O. 219, A. G. O., September 24, 1885.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM SEPTEMBER 13, 1885, *TO SEPTEMBER* 26, 1885.

MURRAY, J. M., PASSED ASSISTANT-SURGEON.—Resignation accepted, to take effect January 1, 1886.

ROSS, J. W., SURGEON.—To special duty at New York.

DUNGAN, J. S., MEDICAL DIRECTOR.—Waiting orders.

PHILADELPHIA, OCTOBER 17, 1885.

ORIGINAL LECTURES.

CLINICAL LECTURE
ON IDIOPATHIC PYELITIS AND RHEUMATISM.

Delivered at the Philadelphia Hospital

BY EDWARD T. BRUEN, M.D.,

Physician to the Hospital, and Assistant Professor of Physical Diagnosis in the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M.D.

IDIOPATHIC PYELITIS.

GENTLEMEN, — The appearance of this patient indicates that he is suffering from some condition which has seriously depressed his vitality. His eyes are sunken, his face is wasted, and his whole body is thinner than is natural with him. Inquiring into his history, we find that during the past three or four months he has been subject to occasional chills, followed by flushes and sweating. Since admission into the hospital his temperature has ranged between 99° and 101°. These symptoms would at once suggest that there is a centre of suppuration in his body. As a matter of fact, its location was speedily decided by an examination of the urine. On standing, the urine threw down a white deposit, which, upon microscopical examination, proved to be pus. The reaction of the urine was acid. These points would suggest the existence of pyelitis.

The diagnosis of pyuria is comparatively easy, although the exact cause of the pyuria is often obscure. In the first place, let me give you the special points that would indicate that the pus was formed in the kidney rather than in the bladder, and then I shall speak of the causes of pyelitis. When pus originates in the pelvis of the kidney, it will in all probability be passed mixed with urine, which will preserve its normal reaction, being either neutral or acid. On microscopical examination, the pus-cells will probably be found not associated with many of the epithelial cells of the genito-urinary tract. Let me here call attention to a point which is of some consequence where the pyelitis is recent: it is that the pus-cells are usually round in what we might call the physiological type. An unfavorable deduction is always to be drawn if the pus-cells are irregularly shaped.

In this case we have the ordinary pus-cells, giving us the idea that the cause of the formation of pus is recent. Such signs would indicate simple pyelitis. But suppose that associated with pyelitis there was a suppurative process going on in the kidney, what would be the evidence of such process? Probably the formation of a few casts, as a rule accompanied by some renal epithelium. Such appearances, indicating involvement of the kidney-substance, are quite important to recognize in connection with pyelitis. The points which would indicate that the pus came from the bladder would be the following: pus from the bladder is usually mixed with the epithelial cells of the bladder, and it is also mixed with mucus, for in cystitis there is a formation of a large quantity of mucus. Further than this, the reaction of the urine will probably be alkaline. This alkalinity is produced by the presence of volatile alkali, such as ammonia, which is characteristic of the alkalinity due to cystitis. The ammonium carbonate is developed in the bladder by fermentation of the urine, which is brought about either by the presence of bacterial organisms or by the formation of a ferment in the bladder. The presence of this volatile alkali is shown by the existence of crystals of ammonio-magnesian phosphate. In addition, the urine will be passed frequently, and its passage will be attended with pain. There will also be in such cases a constant desire to urinate. This man has not had these symptoms.

There is one other point to which it may be well to allude, although it does not strictly come up in this connection: that is, the recognition of pus in the urine from the prostatic portion of the urethra. It seems to me that the most reasonable way of estimating the source of the pus is by separating the urine into two portions, having the patient pass the first portion into one vessel and the remainder into another. If the pus comes from prostatic disease it will be found in the first portion, while the second portion will be free from pus. In other respects the urine of prostatitis has the same general characteristics as the urine of cystitis.

Although a study of this case makes it

probable that the pus originates in the pelvis of the kidney, I am sorry to say that we are unable to detect a definite cause for the pyelitis.

Inflammation of the pelvis of the kidney is in very many cases, perhaps in the majority, due to extension of inflammation from the bladder, and this is brought about by enlarged prostate, by stricture, by cystitis following urethritis, or some inflammation of the lower genito-urinary passages. In other words, it is a secondary affection. Examination of our patient shows that he is entirely free from any of these predisposing causes of pyelitis. It is next most commonly due to some irritation of the pelvis from the presence of a stone. Such collections are usually made up of uric acid or oxalic acid. The best means of determining the presence of such formations is by examining the urine and recognizing the existence of an undue proportion of uric or oxalic acid. These are not present in this case.

Let me refer to the pain of which this patient has complained. He has had a great deal of pain over the lumbar region. Taking into consideration the pain, the emaciation, and fever, together with the fact that two weeks ago I showed a case of abscess of the liver opening in the lumbar region, I thought there was an urgent necessity of examining the hepatic region in order to determine whether or not there was any suppurative process in progress. Abscess of the liver is often latent, and, as in the case I referred to, it may be complicated with cystitis. We eliminated the probability of the pain being due to abscess of the liver by the fact that, under rest and treatment directed to the pyelitis, the pain has almost entirely disappeared, and, further, the liver is apparently perfectly normal, as examined by physical diagnosis. Abscess of the liver would certainly be attended with enlargement of the organ. The pain from pyelitis due to the presence of a stone is very severe and lancinating in character, but at times it will disappear. It will also often be attended with the escape of a little blood, from the irritation of the pelvis by a spicula of the stone. Blood has never been passed by this patient, and there are no signs to make the existence of stone probable.

Pyelitis sometimes occurs in connection with certain blood-poisons, such as the fevers, but he has suffered from none of these. It is sometimes due to pressure upon the ureter by a tumor in the abdominal cavity; but there is no evidence of such a tumor here, nor is there any history of traumatism.

Having considered all the different causes of pyelitis, I am forced to conclude that this is a case of idiopathic character, possibly due to cold, although I am reluctant to admit the influence of cold as a cause of pyelitis.

The treatment is, of course, rather unsatisfactory, since it is difficult to affect this portion of the genito-urinary tract without acting upon the general system. Pyelitis is an extremely obstinate affection, and is apt to cause irritation of the kidney, leading to the formation of what is known as surgical kidney, followed by hectic and general blood-poisoning. The treatment is unsatisfactory because, after pyelitis has continued some time, there is, either from thickening of the pelvis of the kidney or the development of a stone, retention of urine, and pressure is brought to bear upon the kidney, leading to the formation of cystic kidney or causing surgical kidney. The patient is then apt to succumb from general exhaustion.

Where the disease is amenable to treatment, the best results are secured by the use of milk-diet. This gives a small amount of organic matter to be passed out through the kidney, and consequently the urine is non-irritating. That may be put down as the first element of treatment.

The second is to administer such remedies as will produce an alkaline state of the urine. On the whole, I think a combination of phosphate of sodium, bicarbonate of potassium, and some preparation of lithium is best calculated to produce this result. The following may be administered:

℞ Sodii phosphatis, gr. xxx;
Potassii bicarb., ʒj;
Lithii carbonatis, gr. v vel xv. M.

This may be given in a glass of water once or twice a day. It will render the urine alkaline and will not affect the digestion.

In addition to this, it is advisable to employ some preparation intended to act on the pelvis of the kidney as a slight stimulant. The oil of sandalwood has been recommended under these circum-

stances, but I have never derived a great deal of benefit from it. This, however, gives us the line of treatment to be aimed at. Some stimulant diuretic should be administered. The oil of sandalwood or the oleoresin of cubebs may be given. There is another remedy which sometimes seems to have a decided effect upon the mucous membranes: this is boric acid. Boric acid and potassium bromide, in emulsion with oleoresin of cubebs, constitutes an admirable treatment. During convalescence some preparation of iron is to be cautiously used to restore the crasis of the blood. This may be given in the form of Basham's mixture.

In considering this subject there is another matter to be referred to. Is this condition likely to cause abscess around the kidney? Is any direct treatment of the pyelitis possible? Operative treatment in pyelitis—that is, where there has been no stone—is not considered admissible by surgeons; but in these days, when so much is attempted in surgery, if the condition of pyelitis has been caused by a calculus, operative measures have frequently been adopted for the relief of this condition. Persistent pyelitis can produce sufficient irritation in certain cases to develop perinephritic abscess. This should always be remembered as a possible complication. The persistent pain in the back which was complained of in this case led me to examine carefully for the existence of perinephritic abscess, but no signs of this condition were detected.

RHEUMATISM.

I have two cases of rheumatism which I now desire to show you. This first case presents some special features of interest. You observe this peculiar claw-shaped contraction of the hands, which is bilateral. There is also an almost total loss of the electrical reactions in the extensor muscles on both sides. Looking at the joints, we might at first sight think that he was suffering with rheumatoid arthritis, but examination of the joint shows that there is nothing of the kind. A peculiar pear-shaped alteration of the joints of the fingers observed in rheumatoid arthritis is absent. Nor is there the characteristic alteration in the cartilages. The deformity of the hands is due to the excessive action of the flexors of the forearm, as opposed to the extensors, which are atrophied.

Rheumatism is ordinarily considered to be a blood-disease connected with some alteration of the crasis of the blood. This idea is true in so far that there is alteration of the crasis of the blood in rheumatism; but there are certain points which show that rheumatism is a possibly nervous affection, and that the alteration in the blood is a secondary condition. Rheumatism is a disease that comes on suddenly, and often goes away as quickly as it came. Our second patient came in one week ago, with a temperature of 102°, and suffering with pain in the joints, the right arm and the right leg being most markedly involved. To-day he is almost entirely free from pain, and the temperature is normal. In this case the affection appeared suddenly in one or two joints, and has rapidly disappeared under treatment. I shall show you in a few minutes that the treatment is directed more especially to the nervous system. Another fact pointing to the nervous origin of rheumatism is its tendency to fly around from one joint to another. This would not be likely if the disease were a blood-poison. In this man, D., we have a clear history of rheumatism affecting both wrist-joints and associated with this peculiar change in the muscles. In the *American Journal of Medical Sciences* there appeared, a number of years ago, an article on rheumatism as connected with changes in the spine, by Prof. J. K. Mitchell. He had observed that in a number of cases of Pott's disease symptoms of rheumatic inflammation of the joints appeared. Here we have a patient who has not Pott's disease, but he has bilateral atrophy of the muscles, with loss of electrical reactions: such changes as take place in chronic poliomyelitis. Since the affection is bilateral, it seems to me that the only reasonable deduction is that in this patient there has been some condition directly connected with the spine which has been responsible for this atrophy; and, in all probability, the lesion in the spine is responsible for the rheumatic symptoms. Time will not permit me to go extensively into this subject, but I wished to refer to these particular points because they bear so closely on the modern treatment of acute rheumatism.

When we come to treatment, we recog-

nize that we have a disease accompanied with severe pain, with high temperature, and localized inflammation in the joint. The modern treatment of rheumatism, as you well know, consists in the administration of some preparation of salicylic acid. This drug, when successful, relieves all the symptoms. It relieves the pain so speedily that it is evident that it does so through its effect on the nervous system. It lowers the temperature quickly. The high temperature in acute rheumatism, as in many other conditions, is an evidence of disturbance of the nervous system. Fever is, in all probability in the majority of cases, a neurosis. I think that Dr. Wood has abundantly shown that the application of heat directly to the brain, to the heart, and to certain portions of the nervous system is capable of producing all the phenomena of fever, —viz., increased circulation, nervous disturbance, and increased production of heat. The fever of rheumatism is probably quickly relieved because it has this neurosal origin. The physiological action of salicylic acid closely resembles that of quinine: it produces tinnitus in the ears, blindness, and so on. We therefore presume that it acts through the nervous system to subdue pain and lower temperature. It has been found better to combine the acid with an alkali. We give it in connection with sodium or ammonium because we recognize a change in the blood, which also is probably due to the same cause. The assimilative organs are affected by the disturbance of the nervous system, and the blood is therefore loaded with imperfectly-reduced albuminoids. These give rise to the formation of lactic acid and other derivatives of globulin, which are ordinarily eliminated in the form of uric acid and its combinations. Physiologically, these are elaborated into urates of soda and potassium. We therefore give salicylic acid in combination with sodium, ammonium, or potassium, to favor the elimination of these materials as urates. My favorite prescription is the following:

℞ Acidi salicylici, f℥j;
Ammonii carbonatis, gr. 1;
Syrupi et aquæ, q. s. ut ft. ℥ii. M.

This is to be taken in divided doses in the course of twenty-four hours. In this prescription we secure the stimulant effect of the ammonium carbonate and thus obviate the depressing effect of the salicylic acid upon the circulation. If the symptoms are not controlled in thirty-six hours, the amount administered in twenty-four hours may be increased to ninety grains. I never feel safe in going above this amount, but, if unsuccessful, resort to other plans of treatment.

Both these patients have been treated by salicylates. I have, however, another patient in the wards, in whom a good result has been brought about by the administration of twenty drops of oil of gaultheria every two hours for thirty-six hours. The remedy was continued in ten-drop doses every two hours for twenty-four hours longer.

From these considerations I think that we may conclude that the nervous element is the preponderating element, and that the blood-poison is secondary. There are many cases of rheumatism in which the disease is subacute or chronic and is not affected by this treatment. Under such circumstances we may infer that there has been so much accumulation of partially-reduced albuminoids in the blood, so much blood-poisoning, if we may use the term, that the crasis of the blood cannot be restored at once. Recognizing this, I never give salicylic acid without also giving something to render the urine alkaline, for we know that the uric-acid series of products will stand the best chance of being eliminated under such circumstances. For this purpose I give bicarbonate of potassium. This may be given in the form of a lemonade, or the citrate may be given in the same way, or, in the very chronic cases, in the combination of the phosphates with lithium already mentioned in the treatment of pyelitis. As soon as the urine is alkaline, the dose of the alkali should be reduced to such a point as will keep the urine in this condition. An injudicious persistence in the alkaline treatment tends to alter the crasis of the blood, and it is therefore advisable to use the tincture of the chloride of iron or other tonics in case an anæmic condition should supervene. These are the principles of treatment aside from diet, which, it is important to observe, should be of such character as will not supply the albuminoids in too great abundance, and should consist principally of milk, oat-meal, and similar substances. The patients will continue this regimen, and will be brought before you again in order to show you the results.

ORIGINAL COMMUNICATIONS.

REPORT ON OPHTHALMOLOGY.

BY ALBERT G. HEYL, M.D.,
Ophthalmic Surgeon to the Episcopal Hospital.

THE CASE OF HEINRICH HEINE.

HEINE, the famous German poet and critic, suffered during the later years of his life with a distressing cerebro-spinal disorder, which terminated fatally February 17, 1856. Mauthner has collocated the symptoms of his case, from which it appears that the cerebral affection was what is clinically known as nuclear paralysis. Beneath the floor of the fourth ventricle, about the aqueduct and in the adjoining part of the third ventricle, are a number of nuclei to which the nerves of the eye have been traced. When several of these nuclei become diseased we have the condition generally known as ophthalmoplegia or nuclear paralysis. The clinical history of this condition is well illustrated in this case of Heine, which is given in the form in which Mauthner presents it. The sequence of the symptoms, as will be observed, was as follows: Protracted headache, dating back some fifteen years previous to the first eye-symptoms, which were mydriasis and paralysis of accommodation. About eight years later, paralysis of the muscles of the eyeballs, with ptosis, the fifth pair also being involved. Then paralysis of deglutition, difficulty in breathing, paralysis of the jaw-movements, spinal spasms,—death, some thirty years after the inception of the disease.

In the year 1822, during his residence in Berlin, Heine suffered much from nervous headache, which steadily increased during the succeeding years. In the year 1831 Heine resided in France, and for a few years succeeding this date the headaches seem to have diminished in frequency and severity, as there are fewer references to them in his letters of this period. In autumn of 1837 mydriasis, with accommodation-paralysis, occurred. This disappeared after a time, but again recurred. In January, 1845, paralysis of the eye-muscles followed, so that there was paralysis of all the muscles of the eye, both exterior and interior. In the L. E. there was complete ptosis; in the R. E. partial ptosis. The sensitive parts of the trigeminus were also involved. "I kiss," wrote Heine, "but have no sensation with it, so strongly are my lips paralyzed. Also a part of the palate and tongue are affected, and all that I eat has an earthy taste." A little later: "The parts concerned in speech are so affected that I am unable to speak, and for four months I have been unable to eat, owing to the difficulty in chewing and swallowing and the loss of taste." In the spring of 1847 great difficulty in breathing set in. Finally there was paralysis of the jaw-movements, violent spinal spasms set in, the limbs wasted. The back became bowed, apparently from the muscular atrophy. In May, 1848, the patient was obliged to take to his bed, which he practically never left for the remaining eight years of his life. Dr. Gruby thus refers to his condition in 1849. "I found him destitute of all power of motion,—coiled, as it were, together,—the saliva dribbling from the mouth, and utterly unable to feed himself." Violent fits of suffocation developed in 1854–55. On February 17, 1856, he died during an attack of uncontrollable vomiting, possibly brought on by enormous doses of morphia, which had become necessary to him during the later years of his life. A remarkable feature of the case was that the intellect remained clear and bright through all this terrible sickness.—*Mauthner's Vortraege der Augenheilkunde.*

HEAT AS AN ANTISEPTIC IN OPHTHALMIC PRACTICE.

Birnbacher uses heat as an antiseptic in operating in the following manner. All the bandages that are to be used are placed, four hours before the operation, in a closed leaden box and introduced into an oven. In addition, two glass plates with glass covers, after having been washed with solution of corrosive sublimate and alcohol, are also placed in the oven. The air in the latter is then brought to a temperature of about 150° C. and kept there for two hours, and then gradually allowed to cool. Immediately before the operation the tin box is removed, placed on a glass plate, opened quickly, and covered with one of these glass covers, and kept there until the bandages are needed. All the instruments except those used for cutting-purposes are heated in the flame of a Bunsen burner, and laid on the second glass plate and covered with a glass cover. To allow of the heating, the hook, spoon, spatula, and Treber's loop are made of

platinum, and screwed into the ivory handles. The various forceps have the lower third made of platinum. The various eye-drops (cocaine, eserine, atropine) are also heated, the mouths of the vessels containing them being closed with sterilized cotton. The cutting-instruments are placed in absolute alcohol for an hour preceding the operation. After operation the parts about the eye are washed, first with soap, then with the sublimate solution (one to five thousand). Particular attention is paid to cleansing the edges of the lids.—*Centralblatt für Prakt. Augenheilkunde*, August, 1885.

[It is hardly likely that such a complicated method as described above would be maintained. It consumes too much time; and, furthermore, with the greatest care there could hardly fail to be some loop-hole for the entrance of micro-organisms. Aside from cleanliness, it seems probable that the true basis of antisepsis is that of getting the tissues operated on in such a state that if a micro-organism settles in the wound it will find no favorable soil for growth and propagation; and heat properly applied conduces to this end.]

TUMOR OF THE OPTIC NERVE.

Vossius reports the following case. The patient, a servant-girl, æt. 19, had always seen well with each eye. Four days previous to her application for treatment her friends noticed that the left pupil was larger than the right. For a week she suffered with attacks of epistaxis, especially marked during the menstrual period. There was no history of syphilis. At the time of application there was no swelling or redness about the eyelids. The left eyeball was exophthalmic, and rotated downward and outward. The pupil was dilated (*übermittelweit*), did not react to incident light, but to accommodative effort and also to incident light on the other eye there was a slight reaction. The vision was eccentric; fingers counted at eight feet. There was choked disk; very much enlarged, tortuous veins, the tortuosity reaching to the periphery of the fundus. The retinal arteries were extremely narrow. The patient was kept under observation several weeks, during which the vision steadily decreased; the choked disk passed into the stage of atrophy. A year later the eye was completely amaurotic, the exophthalmos was greater. The eyeball with a tumor posterior to it was at this time removed. The tumor proved to be a myxo-sarcoma, extending from the scleral end of the optic nerve to the optic foramen. It was thirty-seven millimetres in length. The outer sheath of the nerve was intact, the inner sheath, the intervaginal tissue, and the interstitial tissue of the optic nerve, but especially the first, being involved in the abnormal process. The optic-nerve fibres, for the most part, were completely disintegrated or atrophied. In other places intact fibres could be traced. Macroscopically, no signs of the nerve-trunk could be detected in the longitudinal section of the tumor.—*Berlin. Klin. Wochenschrift*, March 30, 1885.

COCAINE-INTOXICATION.

Mayerhausen reports the following case of cocaine-intoxication from a collyrium. The patient was a girl, æt. 12, who had injured one cornea by a steel pen. The injury had been followed by a deep discoloration of the cornea. To enable this discoloration to be scratched away, the eye was put under the influence of cocaine by dropping four times, at intervals of about five minutes, one or two drops of a two-per-cent. solution of cocaine (Merck's). During the operation about every five minutes the solution was used, so that about fifteen drops altogether were instilled. Immediately after rising from the operation-table the patient complained of headache, considerable nausea, but no vomiting. There was anorexia for the rest of the day, listlessness, unsteady gait, dulness of mind. These symptoms gradually subsided, it being something more than twenty-four hours before they completely disappeared.—*Klinische Monatsblätter*, June, 1885.

STATISTICS OF ATROPINE-POISONING.

Feddersen (Diss. Inaug., Berlin, 1885) says that there are one hundred and three cases of poisoning from atropine on record, twelve of which were followed by death. Undoubtedly many unrecorded cases have occurred. Of these one hundred and three cases (to which Feddersen adds one of his own, brought about by an atropine salve and followed by recovery), ninety-eight were from prescriptions ordered for internal use, fifty-three from collyria. In nine cases it was given to destroy life (*giftmord*); in ten it was taken with suicidal

intent; eighty-four were accidental. In the cases due to collyria the strength of the solution varied from .17 to three per cent. —*Centralblatt für Augenheilkunde.*

[Hirshberg comments thus on the above: "I have never yet seen a case of atropine-poisoning from the use of collyria." The reviewer has seen decided reddening of the skin ensue, with the milder symptoms of atropine-action, after the use of what purported to be a four-grain solution of atropia. The solution had just been prepared, and it was supposed that the symptoms were due to some susceptibility of the patient. The solution was used once more in another case, and analogous symptoms were developed, possibly not so decided. In neither of these cases were the symptoms toxic, as they required no treatment, but the general symptoms were marked. There can be little doubt but that a stronger solution than gr. iv to f℥j had been inadvertently dispensed.—H.]

VESICLE OF THE CORNEA.

Dimmer describes the following case. The patient—a woman, æt. 30—had received, nine days before applying for treatment, an injury to the left eye from lime. At the time of application for treatment the left cornea was superficially, but over its whole surface, clouded. There was ciliary and conjunctival injection. Atropine was applied and the eye bandaged. Two days later the patient presented herself. The cornea was found to be covered with a large vesicle filled with bloody serum. Instances of the formation of vesicles after burns are on record, but they are rare. A case of Mayerhausen's in which the vesicle was filled with blood, and also a similar one described by Schmidt Rimpler, seem to belong to this category. —*Klinische Monatsblätter*, July, 1885.

PERIODICALLY-RECURRING OCULO-MOTOR PARALYSIS.

P. J. Möbius reports the following: A child, æt. 6, had five attacks of total oculomotor paralysis of the right eye. The attacks occurred at intervals of a year; began with continuous vomiting and violent pains about the eye; lasted, as a rule, eight to ten weeks, when the paralytic symptoms, with the exception of the mydriasis, disappeared. The vomiting before the occurrence of the paralysis lasted eight days, the violent eye-pain fourteen days. The author thinks the cause to be a palpable lesion, which underwent periodical tissue-change. If located near the oculomotor nucleus the violent eye-pain would be accounted for, as the origin of the descending root of the fifth is near this point. —*Centralblatt für die Med. Wissenschaft.*, 1885, No. 5.

INFLUENCE OF CONCAVE GLASSES AND AXIS CONVERGENCE ON THE PROGRESSION OF MYOPIA.

Förster refers to the well-known connection between continuous use of the eyes at a short object-distance and the progression of myopia. Two hypotheses exist:

1. The tensor hypothesis, in which the contraction of the tensor choroideæ is supposed to be the cause of the progression.

2. The convergence hypothesis, in which the increased convergence is the cause.

Förster discards the first, for the form of the eyeball depends on the sclera, and how can the tensor choroideæ induce any change in its shape? Further, were the tensor at fault the myopia would cease after a time to progress, but this does not always happen. All these contradictions cease when we turn to other hypotheses. Förster has observed often that myopics who have worn from youth up pure fully-correcting or even over-correcting glasses never have felt it necessary to change their glasses. This is again contrary to the tensor hypothesis.

The true method, then, of treating myopia is the use of means to prevent too strong convergence, such as the constant wearing of concave glasses. In high grades the use of not fully-correcting glasses is often permissible, but they must be combined with abducting prisms.—*Centralblatt für die Med. Wissenschaft.*, 1885, No. 13.

Dr. W. W. Seely contributes the following upon this subject. Dobrowolsky having asserted that in cases where there is no binocular vision there is no effort at convergence, Seely combats this with the following case. A young lady had a strong divergent strabismus due to a large corneal macula. The other eye was slightly hypermetropic. In spite of efforts at correction, the patient still complained of difficulty in the use of the eyes. For cosmetic purposes, the corneal cloud was tattooed and the right internus advanced. After the operation the patient could read without sense of weariness, and also did not require the correcting-glass for the other eye. In this

case there was absence of binocular vision, and yet the patient was constantly making effort at convergence. Hence the loss of the binocular vision does not indicate that the convergence-instinct has also disappeared. Further, many cases of progressive myopia can only be prevented from advancing by the aid of prismatic glasses. The *rationale* of the treatment of such cases is to aid the diminished convergence-power, which is the main cause of the increased accommodation-effort.—*Klinische Monatsblätter*, June, 1885.

REFRACTION OF THE HUMAN EYE.

Dr. B. A. Randall contributes a critical study based upon the examinations made by different authors, especially among school-children. The various results are tabulated, and thus made of great use to any one interested in this subject.

The following inferences are deduced from them by Dr. Randall:

1. Myopia is almost unknown in infancy, and very infrequent before the period of school-life.

2. Hypermetropia is the enormously-preponderating condition in infancy and early childhood.

3. Astigmatism has been rarely sought with care, and the present data afford no definite conclusions.

4. Emmetropia, in a mathematically-strict sense, has probably no existence.

5. The question of what is normal refraction of the human eye is still an open one.

SOME PRACTICAL SUGGESTIONS IN ELECTRO-DIAGNOSIS AND TREATMENT.

BY LAMBERT OTT, M.D.,

Post-Graduate Instructor in Nervous Diseases and Electro-Therapeutics in the Jefferson Medical College, Philadelphia.

IN the diagnosis and treatment of nervous diseases both a galvanic and a faradic battery are indispensable, and the advice given to students to employ only a faradic battery, as if it answered all purposes, is incorrect and absurd. Both currents are necessary to give one an intelligent opinion of the condition of paralyzed muscles and nerves. In all cases of paralysis an examination is incomplete—more than that, very imperfect—unless you have obtained the electrical condition of the paralyzed parts. In examining a muscle or nerve, place either one of the poles at an indifferent point, over either the sternum or the spine; the former position being preferred, as the patient can hold the electrode in place. If examining a nerve, the other electrode is placed over the nerve at a point where it is most superficial; if a muscle, over its motor point,—the point where the nerve supplying the muscle is supposed to enter,—then note the strength of current required to produce a slight contraction. When it is desired to reverse the poles, as is necessary in the galvanic current, a mechanical contrivance called a commutator or pole-changer is used, which does away with the necessity of lifting the electrodes. This method of examination applies to both currents. Given a case of paralysis, you wish to supplement your examination with an electrical condition of the parts. First examine all paralyzed muscles and nerves with the faradic current, placing the electrodes as previously mentioned. Then ascertain the strength of current required to produce a minimum contraction, and thus you compare the various muscles paralyzed, recording the result for future reference. In most faradic machines the cathode or negative pole is the stronger, and should generally be applied to the diseased parts. If there be no response to the faradic current, the galvanic should be used, applying one pole to an indifferent point, the other over the nerve or muscle, opening and closing the current by an electrode having an interrupting handle,—the preferable way above all other fancy contrivances,—and noting the strength of the current needed to produce a minimum contraction, then compare the degree of contraction of the different poles. When there is normal faradic response there is also an accompanying normal galvanic response, which gives the following formula when the current is opened and closed and the poles reversed,—that is, placing one pole, the anode or positive, on the sternum, the cathode or negative over the nerve, and noting the degree of contraction from a minimum current; then reverse the poles, which places the cathode on the sternum and the anode on the nerve, and interrupting the current: cacc>anoc>ancc>caoc. Examining a healthy muscle in a similar way, the formula is: cacc>ancc>anoc>caoc.

These are the normal muscle- and nerve-reactions to the galvanic current, and almost always can be obtained when the

faradic response is normal or nearly so. But where there is no response to the faradic current there is generally a response to the galvanic, giving a reversal of the normal formula. When a nerve is examined we have: ancc>cacc>anoc>caoc. If the muscle, we have: ancc>cacc>anoc>caoc. The opening contractions are rarely obtained, as the strength of current required is too painful. These formulæ show a condition of partial degeneration, and are called by Erb the reactions of degeneration. One will not always find the order here stated, as sometimes in the muscle-formula we have ancc = cacc, or in the nerve ancc = cacc, both showing a lesser degree of degeneration; but in most cases where the faradic response is absent, there are generally the reactions of degeneration, or there is no response to either current.

There is a prevalent opinion among medical men that if in cases of paralysis one obtains a fair farado-muscular contractility it excludes the spinal cord as the seat of the disease, and places it in the brain. This is a mistake, as certain spinal-cord diseases —*e.g.*, primary lateral sclerosis—give a normal faradic response, or even exaggerated reaction. In all paralyses due to diseases of the brain the electrical reactions are only quantitatively changed, either slightly lessened or exaggerated, but never wholly lost. Even in cases of years' standing there is some response to both currents. Diseases of the spinal cord involving the trophic centres, such as infantile and adult spinal paralysis and acute muscular atrophy, having the seat of their lesions in the anterior horns of the gray matter, usually give in recent cases diminished or lost faradic response, in older cases completely lost faradic response, and either no response to galvanism or the reactions of degeneration. This is especially the case in infantile and adult spinal paralysis and peripheral palsy. In recent cases of infantile paralysis involving the lower limbs I have found that the anterior tibial group of muscles, especially the anterior tibial muscle, was the first to lose faradic contractility. In fact, in all cases of infantile paralysis of the lower limbs either the anterior tibial or extensor communis digitorum muscle is implicated. In acute muscular atrophy, as long as some muscular fibre is left an electrical response is obtained; in advanced cases there is no reaction. In all other spinal-cord diseases, as lateral-column sclerosis (spastic spinal paraplegia), secondary degeneration of the same columns following disease of the brain in the motor tract, post-spinal sclerosis (locomotor ataxia), spinal meningitis, and in the earlier stages of diffused myelitis, there is either normal, slightly diminished, or exaggerated electrical response. If in these diseases you have added atrophy and lost faradic response, then the spinal lesion has encroached on the gray matter of the anterior horns. So it is well to remember, if in long-standing paralysis you obtain fair electrical response to both currents, the seat of the disease is either cerebral or in the lateral or posterior columns of the cord. When there is no faradic response, and the galvanic current shows the degeneration reactions, the cause must be either peripheral or in certain parts of the spinal cord,—the gray matter of the anterior horns.

Let us suppose a case (as Dr. Amidon has in his excellent little work on electro-therapeutics) of paralysis of the extensors of the wrist of several months' standing. The electrodes of the faradic battery are applied, one on the sternum, the other over the musculo-spiral nerve as it winds around the humerus. If normal response is obtained, you must have one of three conditions: either paralysis of cerebral or hysterical origin, or the subject is feigning. If the reactions are exaggerated, it is more likely to be due to cerebral disease. If the farado-contractility is slightly diminished, then it is probably a non-destructive spinal or peripheral lesion. When there is no response to the faradic current, however strong, there must be a destructive lesion in the motor cells of the anterior gray horns, or the musculo-spiral nerve is itself diseased. The same remarks apply to the application of the faradic current to the muscles supplied by this nerve. When the reaction to the faradic current is lost to the galvanic current you generally obtain a perversion of the normal formula, or the reactions of degeneration: that is, instead of having in the nerve cacc> anoc>ancc>caoc, you have anoc>cacc >anoc>cacc. In the muscle, instead of having the normal muscle formula, cacc> ancc>anoc>caoc, you have ancc>cacc >anoc>caoc. This condition shows that the paralysis is either due to a destructive lesion in the motor-spinal cells of the anterior gray horns, or the nerve itself is

degenerated. In the latter electrical condition the diagnosis must be either lead-palsy, antero-poliomyelitis, or injury to the peripheral nerve by compression, etc.; the further history of the case generally aids you in making your decision. When no response is obtained to either current, the causes remain the same, only existing in a greater degree, leading to complete destruction of the spinal or peripheral motor tract.

The electrical condition of individual diseases may be tersely stated as follows. In locomotor ataxia there is normal farado-contractility, with markedly diminished electro-sensibility, especially of the lower third of the inferior limbs. In spastic spinal paralysis there is normal or exaggerated farado-contractility, with normal electro-sensibility. In infantile spinal and adult spinal paralysis, in recent cases greatly diminished or lost farado-contractility; in older cases lost farado-contractility and the reactions of degeneration appear; or, in very old cases, there is no response to either current. In children the two diseases, infantile spinal paralysis and spastic spinal paralysis, at a glance seem very much alike, and often reputable medical men mistake the latter for the former. The electrical reactions will unerringly guide you. In infantile paralysis (antero-poliomyelitis) there is no faradic contractility, but you have the reactions of degeneration or no response to either current. In spinal spastic paralysis (acquired, congenital, or secondary sclerosis of the lateral columns of the cord) there is slightly exaggerated reaction to both currents, with heightened patellar reflex. This differential diagnosis is very important, as the two diseases require different treatment. In progressive muscular atrophy there is faradic contractility as long as any muscular fibres remain; but when they reach a certain stage of degeneration the response to the galvanic current gives the reactions of degeneration. In other diseases of the cord, such as inflammation of the membrane or the cord proper, hemorrhage, concussion, injury, compression, etc., the electrical reactions remain normal or exaggerated unless the motor cells of the anterior gray horns are involved or the peripheral nerves as they leave the cord are compressed or severed. In the latter case there will be, after a time, degeneration reactions or complete loss of electrical irritability. Peripheral palsies, such as are due to compression, contusion, rheumatism, etc., in the beginning present only slightly diminished farado-contractility; later, lost faradic contractility; and if no improvement sets in, the degeneration reactions appear, or all electrical response is lost.

In examining for electro-sensibility, the metallic brush is used with the rapidly-interrupted faradic current. In the treatment of paralysis by electricity only a few general principles can be given. When muscles and nerves respond fairly to the faradic current, apply this form with slow interruptions. Séances of five minutes' duration should be given three times a week, at the same time observing that each muscle should be gently contracted a dozen times or more. Above all, avoid currents which produce violent contractions, or harm is liable to follow. In such cases, having heightened electrical irritability with increased tendon reflex, use electricity sparingly to the muscles. In those diseases where no faradic response is obtained, use the interrupted galvanic current, applying the pole to the muscle giving the greater contraction to the minimum current. In long-standing cases, where the muscles and nerves refuse to respond to either current, the prognosis is unfavorable. I have given such cases patient trials with electricity, and have not accomplished any good. All forms of acute paralysis should be of four to six weeks' standing before any electrical treatment should be instituted. Never overtreat paralyzed limbs by electricity. A good rule which I use was suggested to me by an accident. A man was struck on the shoulder, contusing the circumflex nerve and causing paralysis and atrophy of the deltoid muscle. When I first saw him the muscle gave the reactions of degeneration. I applied for many months the interrupted galvanic current without any improvement. He was suddenly called away, and had to remain without treatment for three months. On his return I found the deltoid muscle nearly restored, the shoulder having its natural rotundity, and a fair faradic response was obtained. My plan is to apply the current about two months; then let the parts rest one month, in which time the patient is to carry out massage; then begin another two months of treatment, followed by a month of rest.

Cases thus treated do much better than those treated continuously for many months without any interruption.

In conclusion, I wish to state that cases of infantile paralysis (antero-poliomyelitis) which present the reactions of degeneration *are* benefited by persistent electrical treatment. I have at present two cases in which, after a year or more of careful attention, I have had good results. If, in old cases presenting these reactions, you have no improvement after eighteen months' treatment, it is probably useless to try any further.

1531 North Seventeenth Street.

"A SEA CHANGE."

BY HORATIO R. STORER, M.D.,

President of the Newport Medical Society, and one of the consulting Surgeons of the Newport Hospital; Ex Vice-President of the American Medical Association.

IT is known to many of the profession that, since returning from the last five of thus far nearly eight years in Europe, I have been studying the adaptability of Newport, Rhode Island, as a general health-station for invalids, similar to those abroad which are recognized as such by American as well as by foreign physicians. Evidence upon this subject I foreshadowed in the *Virginia Medical Monthly* for April, 1879, and have already given in the *Sanitarian* (New York) for January 11, 18, and 25, and February 8, 1883, the *Boston Medical and Surgical Journal* for March 22 and 26, and the *New York Medical Record* for December 22 of the same year. In accordance, however, with a restriction that I had placed upon myself three years previously to the last of these dates, in 1880, I have refrained till now from any decided action towards developing in a professional direction the remarkable hygienic influences of the island.

At the time mentioned I stated, in a communication to the American Public Health Association, that, "though the natural conditions of the place are favorable for health and longevity, I should decline to recommend it (for delicate persons) until there existed a proper system of sewerage; until the soil-water (raised by an artificial public supply) was reduced to at least its natural level; until there were hydrants for fire and general sanitary purposes; until the old cesspools were filled in or removed; until the real estate agents furnished evidence that the houses they offer to strangers are safe to live in; and, over and above all, until there was a board of health-officials who would care for these and other sanitary matters systematically" ("Transactions of the American Public Health Association," vol. vi. p. 216).

During the intervening period the measures thus indicated as essentials have been almost all attained. Newport has now an efficient Board of Health, three members of which are physicians. It has adopted a general plan of sewerage, the main features of which are being rapidly carried out. In proportion as this is done, the level of the ground-water is being lowered and damp cellars made dry. Public hydrants are everywhere. The cesspools and privy-vaults are disappearing. One of the leading real estate firms refuses to lease houses of the better class unless possessing the certificate of the Sanitary Protection Association; and, most recent of all, a mayor and city government have just been elected who are in sympathy with the advances insisted upon by the Association named and by the Newport Medical Society.

Being accordingly free again to express my candid opinion regarding the intrinsic hygienic features of this "American Isle of Wight," I have no hesitation in saying to my medical friends, and the profession generally, that it is worth their while to investigate, personally, if possible, the advantages of Newport as the temporary or prolonged residence of invalids (both medical and surgical, even "hopeless" cases) and convalescents. In doing this I am not merely seeking a selfish end, for, having been appointed by the American Medical Association at its session at St. Louis in 1873 to investigate European health-stations in their relations to American invalids (my report having been rendered at the session in Louisville in 1875), I have felt since my return, a convalescent myself, that, in accordance with the true spirit of my instructions, I am now but pursuing their general subject still further. I will say, in addition, that there are a number of other physicians resident in Newport, members of its Medical Society and personal friends of my own, to whom I shall as gladly see patients from a distance intrusted as though they were sent to my own care. It is needless to add that immediate members of the families of physicians, as always hitherto, will be wel-

come to our best services without professional charge. Good board can be obtained at Newport outside the fashionable season, say from September to July, inclusive, at from six to twenty dollars per week.

The conditions at Newport may be thus briefly stated. Its climate is distinctly insular, to a great extent oceanic, being materially affected by the Gulf Stream, and milder than that of the coast-line, even where this is but a very few miles distant. The seasons are markedly prolonged into each other. The atmosphere, though moist, is decidedly saline. Rheumatism and the various nervous hyperasthenias are rare as here originating, and when brought are almost always relieved. Pneumonia, and even phthisis, save as here for treatment, are exceptional. The winters are comparatively mild, and though snow and ice are of course present for portions of each winter, it is to a much less extent and for a shorter period than upon the mainland. There are many patients who could be made comfortable here during winter who are now carried South, to their own inconvenience and that of their friends, or remain at home in much less favorable local climates.

I can only add that, should chronic cases of any kind, or convalescents, be confided to my charge, I will endeavor to carry out the wishes of the medical men to whom I may owe them. To accomplish this the more satisfactorily, I have associated with myself in practice Dr. W. Thornton Parker (Munich), late Acting Assistant-Surgeon, U.S.A., and together we shall do what we can to make Newport generally recognized, aside from all its social attractions, as a valuable therapeutic aid to the American medical profession.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE HOSPITAL.

CLINIC OF JOHN H. BRINTON, M.D.,

Professor of Clinical Surgery, Jefferson Medical College.

EXCISION OF THE SCAPULA FOR SARCOMA.

GENTLEMEN,—The specimen which I present for your inspection is that of a tumor taken from a girl 11 years of age, upon whom you saw me operate at our last clinic. The growth involved the entire right scapula, and was the result of an injury received two years ago. At that time the child fell down a slope about seven feet, striking her scapula upon a projecting stone. There was a little temporary pain, but in an hour this had passed away, and the incident was forgotten. In April of this year she complained of some tenderness over the back of the shoulder, and about May a lump or swelling was noticed by the parents. This grew rapidly in size until, as I showed you at the last clinic, it measured fifteen inches in diameter and the shoulder was very prominent. The scapula also seemed to be thrust away from the side of the chest, and a hard lobulated mass could be felt deep in the axilla. With these local changes the constitutional condition of the child sympathized to a marked degree. The pain at times was very great, occurring at intervals during the day, and more constantly at night. Sleep became almost impossible, and of late could only be obtained by the free use of opiates. The child was evidently going down rapidly; the persistent suffering, the loss of rest, and the poisonous impression of the growth were wearing her out. There was no hope for her, save in an operation for the removal of the mass. After due consultation and reflection, I determined to attempt the extirpation of the growth, having first plainly set before the parents and the grandfather of the child the great peril of such an operation, and having explained to them the possibility of a speedily fatal result.

I accordingly excised the entire scapula in your presence four days ago. I then drew your attention to the care and caution employed in the administration of the ether, and to the efforts made, and successfully made, to prevent bleeding. So efficient were the exertions in this direction that, as you noticed, very little hemorrhage occurred. I do not think more than four or five ounces of blood were lost, the vessels having been perfectly temporarily constricted before being divided and tied. The command of the subclavian was also absolute. Yet, with all these precautions, the patient died about an hour after the completion of the operation. She had previously emerged from the influence of the anæsthetic, and had spoken rationally, and answered questions. The action of the heart, however, suddenly flagged, and death occurred despite active stimulation

and hypodermic medication. The death was one from surgical shock, and could not have been prevented.

Here is the growth: it is a lobulated, sarcomatous mass, involving the infraspinatus and subscapular fossæ, stretching but not infiltrating the muscles; the indurated axillary mass is a part of the subscapular growth. The overlying skin is healthy.

You are not likely to see many such cases,—this being only the second excision of the entire scapula for disease done in this city, to the best of my knowledge.

GONORRHŒAL EPIDIDYMITIS.

I brought a man before you at our last clinic suffering with gonorrhœal orchitis, and then told you that the term orchitis was not to be taken in the strict sense as inflammation of the testicle, for in many cases the epididymis only is involved. I now present to you James F., 26 years of age, with an enlarged testicle following an attack of gonorrhœa, who has epididymitis, not orchitis. This is very likely to occur in cases of gonorrhœa, and you find upon examining the testicle in such cases that the swelling is at first confined to the epididymis, involving the globus major or minor, or both, and you will detect a crescentic mass of induration (due to the inflamed epididymis), and in the cup-shaped depression rests the testicle. Subsequently the testicle may become inflamed, or an effusion occur into the tunica vaginalis, giving rise to great pain and hardness.

It is a fact worth noting that the pain is not necessarily felt in the testicle. This man complains of pain in his back, in the groin along the spermatic cord, and extending along the branches of the genito-crural nerve down the thigh, even down to the leg,—rather than in the testicle itself.

How shall you treat this affection? If a case of acute epididymitis come to you for treatment, you should direct the patient to lie down upon his back with the scrotum elevated, so as to drain the venous blood away; and cold applications of lead-water and laudanum may be made to the inflamed organ,—or they may be tepid if the patient cannot bear the cold. If the bowels are not open, give the man a dose of salts, Epsom or Rochelle, a teaspoonful each morning. If the pains are severe, opium may also be given; and if the inflammation is very marked, two or three ounces of blood may be taken by leeches. I know that it is said that leeches should not be applied to the scrotum, on account of the ecchymosis which they cause; but in such cases looks are of less importance than prompt relief. The lead-water will have to be washed off before the leeches will take hold. After the acute symptoms have passed, I am in the habit of applying mercurial ointment upon a piece of lint, with which the extract of belladonna may be incorporated in proportions up to one-half that of the mercury. This is to be applied fresh every morning; before doing which the scrotum is to be carefully washed off with warm water and soap, to get off the old ointment. Under this treatment the patient will usually get well in about two weeks, but there will generally remain a tell-tale button of induration in the globus minor. When you find this significant little witness, you need not test the patient's veracity too greatly by asking if he ever had gonorrhœa and an inflamed testicle.

The treatment of epididymitis, then, may be summed up as rest, support for the testicle, saline purgatives, leeches, and anodyne applications of lead-water and laudanum, with morphine internally if necessary. The diet should be restricted.

CASES OF EXOSTOSIS.

From this boy, at the last clinic, I excised a small ivory exostosis from the frontal bone over the right orbit. You remember that I had some difficulty in removing it, on account of its hardness; but I finally did so with a saw, and smoothed the surface with a rasp. Corrosive-sublimate (1–1000) dressings were applied, and the wound healed without suppuration. He is now well.

Here is a man from whom I removed an enchondromatous growth attached to the tendinous and fibrous structures of the first phalanx of the ring-finger, of slow development. I took away, from an incision along the palmar surface of the phalanx, a large quantity of loose material, and necessarily inflicted considerable injury. The wound was washed out with corrosive-sublimate solution, and the hand put upon a splint. There was no marked inflammation, and the motion in the neighboring joint is

good. Here is an important point: in all operations in the neighborhood of joints, you should insist upon early passive motion; otherwise you may get a stiff joint. Keep the joint in motion, in order to preserve its function.

ENCYSTED HYDROCELE OF THE CORD.

This infant, 4 months old, has an accumulation of fluid in the pouch of peritoneum which accompanied the testicle down into the scrotum, and which has had its canal obliterated above and below this point. The swelling was noticed shortly after birth, and has since increased in size.

This condition does not require much treatment. Cold applications of chloride of ammonium solution or of lead-water will favor its absorption; or it may be got rid of more rapidly by a few punctures with the needle. The irritation of the punctures will be sufficient to excite inflammation, and obliteration of the sac will perhaps follow.

INJURY OF ELBOW-JOINT BY A FALL.

This girl, 12 years of age, fell four weeks ago, and was supposed to have received a dislocation of the elbow-joint. The question is, Did she receive a dislocation? I have not yet examined it. Let me say that these cases require careful diagnosis. I will never risk my reputation by pronouncing upon a case like this without examining the patient under ether.

Is the head of the radius in its proper position? Many do not know how to find the head of the radius. Let me show you how to do it. In a normal arm, if you flex the elbow-joint, you can find the external condyle; then, by extending the forearm, you notice a pit or depression just below the condyle, marking the position of the head of the radius. Grasp the joint so that your thumb rests upon the external condyle, and then, flexing the forearm, let the thumb slip down into the depression, where it will detect the rotation beneath it of the head of the radius when the hand is pronated and supinated.

Applying the test here (the patient being anæsthetized), I find the head of the radius in position, and it rotates as I pronate the hand. I find some crepitation, due to adhesions which have formed during these four weeks. The motions of extreme flexion and extension are resisted by these adhesions in the joint, but there is no evidence of dislocation or of fracture involving the joint. This passive motion must be practised daily as soon as the effects of this manipulation shall have subsided under applications of lead-water and laudanum. The joint will be liable to be stiff for some time, and to prevent this she shall employ passive movements, massage, and exercise, such as carrying a coal-scuttle up and down stairs and boring holes in a piece of pine wood with a gimlet, every day.

CASES OF NECROSIS.

[Three cases of necrosis were shown, which did not require special comment or immediate operation.—Rep.]

FISTULA OF THE ANUS.

Mr. S., 42 years of age, comes before us for treatment for fistula. I would define a fistula as a sinuous channel connecting internally with the cavity of the bowel and externally with the skin. Ordinarily commencing with ulceration of the mucous membrane in one of the pouches of the rectum, just within the sphincter ani muscle (which acts like the purse-string to a bag), the ulceration penetrates the submucous tissue and allows fluids to burrow downward through or by the side of the sphincter muscle. An abscess is thus formed which points externally, bursts, or is incised, and so remains permanently open. Several sinuses may thus be created, or the pus may travel upward and make a secondary opening into the rectum. In other cases, as the result of a kick, or a fall, or a blow, or from some other cause, an abscess may arise in the cellular tissue around the anus, and discharge itself externally, or internally into the rectum, or both.

Now, as to treatment, be careful to find the true or original internal opening. First introduce a flat-handled probe, such as this of Sir Benjamin Brodie, through both openings, with the aid of a finger introduced into the rectum. Remember, the internal opening is most usually just above the sphincter; if there is another one higher up, it is secondary. Follow the probe with a grooved director, the extremity of which is then brought outside the anus; the overlying ring of tissue is then cut by a bistoury along the grooved director, and the old fistulous track scraped with the handle of

the knife in order to remove the old, unhealthy granulations.

[Having performed the operation upon the patient, a compress dipped in carbolized oil was applied, covered with a towel, and the whole kept in place with a T-bandage.—Rep.]

SCIRRHUS OF MAMMARY GLAND.

Mrs. Mary R., 45 years of age, comes from Delaware for an operation, and gives the following history. She menstruated at fourteen years of age, was married at twenty-five years, and has had two children. In the spring of 1881 her attention was first drawn to her right breast by shooting pains. Shortly afterwards she noticed a hard lump just above the nipple, which up to this time had been normal, and neither of the nipples had presented any signs of skin-disease. Afterwards the nipple became retracted and enlarged. Since April of this year the tumor has grown very rapidly, and has been more painful, more so at night than during the day, and worse during a storm. Now the breast is hard, lobulated, the superficial areolar glands are enlarged, the nipple is retracted, enlarged, and resembles a ripe strawberry. From around its ulcerated base exudes an offensive discharge. The patient's general health is good. The gland is beginning to be attached to the overlying skin. Some enlarged glands are found in the axilla.

Scirrhus is the form of carcinoma most frequently encountered in advanced life, and in married women the mammary gland is the most common site.

In this case nothing can be done except extirpation of the breast, which shall be removed with the overlying skin, the whole gland being included in two curvilinear incisions.

The instruments employed have been disinfected by immersion in a carbolic-acid solution, and the hands of the surgeon and his assistants are also washed, just prior to the operation, in a solution of corrosive sublimate.

[The operation was performed, and the diseased gland and axillary lymphatics removed, care being exercised to take out every indurated gland which could be detected in the axilla. A compress wet with corrosive sublimate was applied over the wound, after its edges had been approximated with the interrupted suture, and powdered with iodoform.—Rep.]

TRANSLATIONS.

Bromhydrate of Quinine.—Among the various preparations of quinine the bromhydrate has some characters which deserve special attention. It contains from seventy-five to seventy-six per cent. of quinine in a purer state than that entering into the sulphate; it is soluble in sixty parts of water; the solution is acid, and clear, but after a few days presents a greenish tint. Dr. Maximowitsch (*St. Petersburger Med. Woch.*, 1884) finds its sedative action of special value in fevers, and has employed it in acute pneumonia, typhoid fever, scarlatina, variola, phthisis, etc. After a hypodermic injection of from .60 to .90 (gr. x to xv), or one dose of from .60 to 1.20 (gr. x to xx) by the mouth, the temperature falls in grave cases from 0.4° to 0.8° (C.), and in light cases from 1° to 1.5° (C.), and the pulse is retarded 10 to 30 pulsations per minute. This improvement persists several hours, then the temperature increases again, while the pulse remains slow for two or three hours more. The patient becomes calm, sleeps quietly, and the delirium ceases.

In phthisis the bromhydrate of quinine has shown itself to be a useful antipyretic, especially when the patient cannot bear narcotics.

Its action in intermittents is like that of other salts of quinine, but it is especially valuable in malarial neuralgias. In one case of quotidian intermittent it proved efficacious in curing the patient, after the failure of sulphate of quinine and Fowler's solution. In cerebro-cardiac neuropathy and neurasthenia it was also used with success. Where anæmia is marked, it may be combined with the bromide of iron.—*La France Médicale.*

A New Therapeutic Method: Dielectrolysis.—At the meeting of the Academy of Medicine (Paris, September 22), Dr. A. Brondel read a communication with regard to the introduction of remedies into the system by means of electricity. The method is based upon the principle that if a current is made to pass through a saline solution the metal will go to the negative pole, and the metalloid, in certain salts, or the acid, goes to the positive pole. The salt is decomposed. It is this that Dr. Brondel has succeeded in conducting

through the animal organism, and to which he gives the name of dielectrolysis.

For iodine, which is easily dielectrolyzable, he applies upon the surface of the body a sheet of amadou wet in a solution of iodide of potassium, and above this sheet he places the negative pole of a pile, of which the positive is placed upon some other part of the body: the iodine then separates from the potassium at the negative pole and travels across the tissues towards the positive pole, where it soon appears, as is shown by a starch test-paper. This is a hypodermic method of medication without breaking the skin, and without pain.

Quite a number of simple bodies may be made to traverse the tissues in this way, and the applications of the new method may be very numerous and very important. Dr. Brondel claims to have thus cured uterine fibromata, a case of perimetritis, a rheumatic neuralgia of the ovaries, and several cases of chronic rheumatism.

Later investigations suggest applications to other diseased states: to parasitic and malignant tumors, skin-diseases, syphilis, neuralgia, etc., and especially pulmonary phthisis, where Dr. Brondel intends trying the action of different mineral antiseptics, such as arsenic, mercury, fluorine, which dielectrolysis will permit to penetrate the pulmonary tissue.—*La France Médicale.*

[This method of treatment can scarcely be considered novel. Priestley and others in the last century made experiments upon the electrolytic conduction of medicines through animal tissues, which were subsequently revised and extended by Klencke (1845), Hassenstein (1853), and Clemens (1860). Beer, of Vienna, in 1869, called especial attention to the electrolytic conduction of iodine in the manner above stated; but experiments made by Von Ziemssen, Brückner, and others proved the erroneousness of these views and the impossibility of obtaining the desired effects, owing to the resistance offered by the skin, and because it was found impracticable to conduct the iodine to great depths through complex animal tissues. The cataphoric effect obtained in Munk's experiments upon the galvanic introduction of different fluids into the uninjured human and animal organism, however, deserves more serious attention. Consult Ziemssen's "Hand-Book of General Therapeutics," vol. ii. page 388 *et seq.*—Ed.]

The Etiology of Tabes Dorsalis.—Dr. Belugon, in a communication to *Le Progrès Médical*, entitled "Recherches sur les Causes de l'Ataxie locomotrice progressive," concludes that:

1. No cause can be invoked as possessing the exclusive monopoly, or as being an element necessary to the production, of locomotor ataxia.

2. The etiological elements which seem to have the greatest importance in the pathogenesis are syphilis, nervous heredity, rheumatism, and functional abuse.

3. In nearly all of the cases, besides the other etiological circumstances, functional excess and nervous over-strain play an accessory *rôle*, and contribute in a more or less marked manner to the evolution of the disease.

4. The etiology of tabes may be formulated in the great majority of cases thus: In an individual possessing a nervous temperament, whether hereditary or acquired by functional abuse, or (as almost always happens) the first exaggerated by the second, together with an occasional cause,—accident, cold,—with, and nearly constantly, the localization of one of two diatheses, syphilitic or rheumatismal, it occurs in the spinal cord. Such is the common origin of progressive locomotor ataxia, according to the author.

Thalline.—Strongly resembling kairine, thalline belongs to the chinoline series, and technically is *tetrahydroparamethyl oxyquinoline*. On account of the green color which it produces when brought in contact with the chloride of iron, the name of thalline was proposed for it by Skraup, the discoverer of this agent. The salts employed in medicine are the sulphate and tartrate. The sulphate is very soluble in boiling water, and dissolves in five times its weight of cold water.

Jacksch, of Vienna, has shown that it lowers the temperature in comparatively small doses (twenty-five to thirty centigrammes), and without causing sweating. Dujardin-Beaumetz declares that thalline is the most powerful of antithermic agents, but on account of its destructive action upon hæmoglobin it should be used with caution, and only in relatively small doses, not exceeding twenty-five centigrammes (four grains).—*Bulletin de Thérapeutique*, August 30.

MEDICAL TIMES.

PHILADELPHIA, OCTOBER 17, 1885.

EDITORIAL.

CELLS *VERSUS* BACTERIA.

WITH the completion of the centennial volume of his *Archiv* and the opening of a new series, Virchow discusses, in one of those keen, sharp reviews with which the readers of his journal are from time to time indulged, the burning question of the day: the battle of the cells and the bacteria. With the establishment of his journal, forty years ago, the great advance of organic chemistry had turned the minds of investigators in that direction, and it required no little courage to maintain the honor of biology; but the rapid progress in the knowledge of the minute structure of animals and plants finally led to the substitution of "*omnis cellula e cellulâ*" for Harvey's famous dictum, and placed the cell-theory of life and the cell-theory of disease on apparently sure foundations. More and more had we come to regard the ultimate histological elements of the tissues as the seat of the processes through which life is manifested. Nay, more! We had arrived at the conception of the cell as an *entity*, living its own special life and possessing a sort of individuality or personality. But now all seems changed. Micro-organisms have taken the front rank in medical interest, and "they rule the thoughts and the dreams of many old and almost all the young men." The cells are forgotten. An amusing extract is given from a Paris journal, in which are such sentences as "*La pathologie cellulaire a vécu*," "*à bas les cellules.*" Upon which Virchow comments, rather ironically, "The poor little cells! No wonder they cannot be seen by the men who use Abbe's condenser,—that most convenient bit of apparatus which permits only the microbes to appear in the field. But there they are, still the most important elements; and, as they are patient, their time will come again, after the physicians shall have filled up by their labors some gaps in botanical science."

An interesting sketch is given of the growth of our knowledge of parasitic fungi from the time of Bassi and Schönlein, and Virchow refers with pride to the many valuable communications on the subject which are to be found in his *Archiv.*

The problem in connection with diseases supposed to be due to micro-organisms is a threefold one: first, the discovery of the parasite; second, the demonstration of its life-history; and, third, the way in which it causes the disease. The controversy is on this last one; and just here we are brought back to the old pathology. Nowhere is this more clearly shown than in the history of phthisis. When Koch discovered the bacillus, there were those who behaved as if all the good work of the past had been useless. As the bacillus was a single entity, so was phthisis; lung-tuberculosis was only caseous hepatization, and gland-tuberculosis scrofula. "In spite of all, pulmonary tuberculosis remains a multiform process, which begins in many ways: sometimes in the mucous membrane of the bronchi, sometimes in the alveoli, and again in the lung-substance, and is accompanied by changes inflammatory as well as tuberculous, and whoever thinks to understand these must learn more than how to stain bacilli."

The battle is between the cells and the microbes,—*i.e.*, between living organisms. At present we know more of the activities and energies of the cells than of the bacteria. Of the great problems to be worked out, one is the relation of the tissue-elements to the various micro-organisms, and the other is the determination

of the distinction between the effects of these bodies and those of the substances they produce. The question of ptomaines has taught us how important the latter aspect is, and, curiously enough, the originally botanical problem becomes more and more a chemical one.

The veteran professor believes that we can still walk in the old ways, and that we need no readjustment of science to bring in the new facts.

THE HEALTH OF AMERICAN WOMEN.

THE question of whether or not a woman should learn the alphabet having by general consent been decided, in this country at least, very positively in the affirmative, the effect of a college course upon her physical health deserves and has received serious attention. The essay by Dr. Clarke on Sex in Education has had a good influence in indicating the only method in which her energies and efforts may be directed in obtaining her education with safety to her physical organism, and in showing incidentally that, if wisely controlled, college privileges may be enjoyed and utilized by women equally with men. Two years ago the Dean of the Women's Medical College of Philadelphia, after making inquiry among the alumnæ, ascertained that the health of the graduates of the school, far from being injured by their studies and mode of living, appeared to be really improved by the culture it entailed and the career of usefulness which had been opened to them. This really might have been anticipated if the criticism of Miss Martineau, that the feeble condition of American women was attributable to the vacuity of their minds, had any foundation in fact. Women are like men in being healthier and happier when pursuing some well-defined and worthy purpose in life.

From a recent investigation by the Massachusetts Bureau of Statistics of Labor it would even appear demonstrated that mental labor is better suited to women than physical. Certainly, at least, it seems established that there is nothing injurious to the health of women in a severe course of study. Of the twelve hundred and ninety women graduates of colleges in this country, seven hundred and five replied to the schedule of questions sent out by the Bureau; and, as these are the first detailed statistics concerning the health of this class of American women, their replies afford information upon several points of interest. From them it appears that seventy-eight per cent. were in good health upon entering college, at the average age of 18.35 years; in two per cent. health was fair, and in twenty it was poor. Deterioration in physical health during the course was observed in 19.58 per cent., amelioration during the same period in 21.13 per cent., the difference being 1.55 per cent. in favor of the college course. The most prevalent cause of disorder among those who studied severely during college life was constitutional weakness. Thirty cases of cerebral affections were reported, and twelve of eye-trouble; possibly some of the cases reported as brain-disorder belonged properly to the latter group. In conclusion, the Bureau of Statistics states that "the facts which we have presented would seem to warrant the assertion that the seeking of a college education on the part of women does not in itself necessarily entail a loss of health or serious impairment of the vital forces. Indeed, the tables show this so conclusively that there is little need, were it within our province, for extended discussion on the subject. The graduates, as a body, entered college in good health, passed through the course prescribed without material change in health, and, since graduation, by reason of the effort to gain a higher education do not seem to have become unfitted to meet the responsibilities, or bear their proportionate share of the burdens, of life."

The *Nation*, in commenting upon this, justly remarks that "Americans have not yet attained the robustness and vigorous color of the parent race, but they can no longer be regarded as a nation of invalids. The fragile and chalky young ladies who were in fashion twenty years ago have given place to young women of clear, bright color and healthy, vigorous step; the hollow-chested ministers and the lean and sallow business-men of a former day have passed away, never, let us hope, to return." Among the immediate causes of this improvement we would award a high rank to the persistent and disinterested teaching of the members of the medical profession, both men and women, notwithstanding the apparent intimation on the part of the *Nation* that the latter are chiefly "engaged in swelling the death-rate."

THE MICROCOCCUS OF GONORRHŒA.

RECENT investigations have led Kreis (*Wien. Med. Wochenschr.*, Nos. 30, 31, and 32, 1885) to the conclusion that the micrococcus first described by Neisser as being always present in gonorrhœal pus is the infective agent in transmitting this disease. Kreis made pure cultures of the gonococcus on a culture-medium composed of agar-agar and meat peptone. Exposure to a temperature of 35°–40° C. (95°–104° F.) was required for free development of the organism. When the temperature was raised to 50° C. (122° F.), there was no development of the micrococcus. This pretty nearly corresponds to the results of Sternberg's investigations into the thermal death-point of various micrococci and other sporeless organisms. Kreis also found that no development occurred in an alkaline culture-medium.

A large number of germicide agents were tried in order to determine the proportion necessary for the destruction of the vitality of the gonococcus. The following were found effective in the proportions mentioned: silver nitrate, .5–1 per cent.; cupric sulphate, platinum chloride, each 1 per cent.; thymol, 1 : 1100.

A number of inoculations of pure cultures upon inferior animals (rabbits and dogs) resulted negatively. In view of the negative results of Sternberg's inoculations of pure cultures upon human subjects, this might have been expected.

These observations of Kreis and of other investigators appear to show that: 1, a micrococcus having peculiar characters is always present in gonorrhœal pus; 2, a temperature of 50° C. (122° F.) and above will prevent the development of this micrococcus, but not necessarily destroy its vitality; 3, a one-per-cent. solution of silver nitrate, cupric sulphate, or platinum chloride, or a one-tenth-per-cent. solution of thymol (more accurately, 1 : 1100) will destroy the life of the organism; 4, pure cultures of the gonococcus are not inoculable upon man or the lower animals.

Although doubts have been thrown upon the specific character of the gonococcus, yet these need not prevent the testing of the practical conclusions drawn from Kreis's paper that the use of hot-water injections (50° C. = 122° F.) is indicated to restrain development of the organisms; and that one of the above-mentioned germicide solutions should be used by injection to destroy the infectivity of the virus. Preceding the use of the germicide, Kreis suggests an injection of a cocaine solution into the urethra to obviate the pain.

Although his culture-experiments failed to demonstrate the germicide action of chloride of lime, Kreis has found this agent, in one- to two-per-cent. solutions, effective in rapidly curing the disease.

DR. E. O. SHAKESPEARE has been appointed by his Honor President Cleveland a special commissioner to visit Spain

and to report to the State Department upon the recent epidemic and its sanitary lessons. Dr. Shakespeare is especially qualified for this work by his bacteriological studies in Koch's laboratory and in his own department at the University of Pennsylvania. The increasing appreciation of the value of state medicine by our government is gratifying and significant. We hope it may lead eventually to erecting a distinct department of public health in our national government, by the presiding officer of which a cabinet portfolio shall be held.

LEADING ARTICLE.

TETANY.

IT is strange that a disease of such frequent occurrence in France and Germany as tetany, and one possessing such marked traits, should be so rarely reported by English and American observers. Possibly some explanation for this may be found in the neglect of many of our systematic writers to mention the disease, while others seem to regard it as simply *tetanus mitis*. Although the pathology of tetany has not yet been definitely established, the morbid anatomy of tetanus has been at least sufficiently investigated to show that they are not identical, and that the difference between the two forms of muscular spasm is one of kind, and not merely of degree. The differential diagnosis of tetanus and tetany was the basis of a paper, illustrated by cases, published by Schuppert some months ago.* In the former he declares the prognosis to be as gloomy as in the latter it is favorable. He says, "Tetanus I am now forced to consider as almost exclusively a complicated wound-disease, with hardly any hope of recovery. *No wound, no tetanus;* though not every case of spasmodic convulsions associated with or following a wound can be called tetanus. The so-called 'idiopathic tetanus' is not a true tetanus, but almost always a *tetany*, a denomination first proposed by Corvisart, and since generally adopted in France and Germany." Local muscular spasms, however, must be excluded from the consideration of tetany, as suggested by the classical description of the disease by Kussmaul, and the strict application of this would reject the first case of Schuppert, in which painful paroxysmal muscular contractions occurred in a stump after a thigh-amputation, owing to the presence of an imprisoned ligature, which afterwards escaped by ulceration, with immediate and lasting relief to the patient. His second case is one of tetany owing to constipation.

A case of intermittent tetany of five years' duration in a patient suffering with chronic diarrhœa has been recently reported by Dr. James Stewart to the Medico-Chirurgical Society of Montreal,† the paper concluding with a few remarks upon the clinical history, pathology, and treatment of tetany, which admirably summarize the present state of our knowledge upon this subject. Three apparently distinct forms of tetany exist, forms which differ much in the causes which give them origin and in their prognosis, though but little in the clinical pictures which they present. The most common is the "rheumatic," or epidemic, variety; the second is more chronic, and is due to either chronic diarrhœa, prolonged lactation, or other debilitating influences. The third form follows operations for removal of enlarged thyroid glands. In the first two recovery is the rule; in the last-named, or surgical variety, early and complete recovery is stated to be very exceptional.

As regards its frequency, Dr. Stewart states that on the continent of Europe it is quite common, and this is true of all forms of the disease. In Vienna not a winter passes without an epidemic of it, while cases of the chronic and surgical varieties are not at all rare. Up to May, 1883, Billroth had performed seventy-eight operations for removal of goitre,—twelve of which proved fatal, six of these being directly due to tetany. In all, there were thirteen cases of tetany following the seventy-eight operations, six of which ended fatally. Two of the fatal cases ran a course of upwards of one year, while the remaining four terminated within two weeks. Clinically, tetany may be distinguished from tetanus chiefly by the fact that the

* Tetanus and Tetany. New Orleans Medical and Surgical Journal, vol. xii. pp. 434, 507.

† Canada Medical and Surgical Journal, August, 1885.

spasms exist primarily in the hands and feet, although in more severe cases the muscles of the trunk and jaws may be affected; but rigidity does not begin in them, as in tetanus. The contractions are not very painful, and usually vary in intensity from time to time, even when a degree of spasm is persistent for days. Tetany shows a special tendency to recurrence, after periods of entire immunity. It is most common in children, and in adults it appears occasionally; but especially is it apt to attack women during lactation.

Should tetanus be proved to be a bacterial disorder, or due to a specific poisonous element present in the blood, it will only furnish additional reason for requiring cases of tetany to be separated clinically from others which they more or less resemble. F. W.

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

THE "French Association for the Advancement of Science" continues its sittings at Grenoble. M. Boucheron, of Paris, presented an interesting article in regard to the régime to adopt in cases of arthritism, particularly when seated in one of the organs of sense. The fact that in all these affections there is an overabundance of the nitrogenous elements (shown by uric acid in the urine, etc.) had led the lecturer to think that an alimentation containing very little nitrogenized matter would be advisable. He cited the case of the celebrated monks at the convent of the "Chartreuse," who live as follows: in summer they have two meals, composed of fish and eggs, vegetables, milk, and a little wine; in winter they take but one meal and a lunch, about the same, but no meat; and, notwithstanding the winter is very long and cold up there, they keep in excellent health. Gout or rheumatism is unknown among them. Even those who are so afflicted when they enter the order get cured by the régime. They have no articular diseases, and skin-disease or asthma has no hold on them. They all live to quite an old age. So that an alimentation containing but little nitrogen is not hurtful to health, but may be given with great benefit, and in arthritic cases may be conjoined with mineral waters and other appropriate treatment. M. Arduin had something to say on the therapeutic action of antipyrine. It seems to have a very special action in diseases of the lungs, principally in tuberculous fever. With small doses of 25 centigrammes to 50 centigrammes, the temperature will fall from one and a half to two degrees. Its action in nervous maladies, in articular rheumatism, and in albuminuria was spoken of, but it was admitted to be much more inconstant here. From some experiments, he had concluded that its action was on the medulla oblongata and the brain; it slows the pulse and causes death by arrest of the heart. Its hæmostatic effects are much more rapid than the perchloride of iron and ergotine, but they are entirely local,—quite different from ergotine. It is also an antiferment, like salicylic acid. The latest use of it is as a suppository for hemorrhoids.

M. Delthil again called attention to his treatment of diphtheria by inhalations of a mixture of coal-gas tar and turpentine. He still thinks that diphtheria is secondary to a primitive inflammation of the tracheo-pharyngeal mucous membrane. The inhalations he regards as the best method of preventing the secondary affection. M. Delthil also spoke of the use of large doses of sulphate of magnesia in cancer of the stomach. He could raise the dose to forty grammes without causing more than one stool a day, as the patient's system got used to it. There is perhaps no cure, but all the morbid symptoms disappear, and there is an arrest of the disease.

In the Anthropological Section, a disciple of Darwin, M. de Mortillet, read a paper on tertiary man. The question, he said, was not to know whether man really existed in the tertiary epoch as he exists to-day. Animals vary from one geological stratum to another, and the higher the animals the greater the variation. It was to be inferred, then, that man would vary more than the other mammals. The problem was to discover in the tertiary period an ancestral form of man, a predecessor of the man of historical times. M. de Mortillet affirmed that there are unquestionably in the tertiary strata objects which imply the existence of an intelligent being. These objects have been found at two different stages of the tertiary period: one in the lower epoch at Otta, in Portugal, and at Puy-Courney, in Cantal. These objects proved that at these distant epochs there existed animals acquainted with the use of fire and able more or less to cut stone. During the tertiary period, then, there lived animals less intelligent than existing man, but more intelligent than existing apes. M. de Mortillet gives the name of *ape-man* to the species, which he maintains was a historical or ancestral form of man, whose skeleton has not yet been discovered, but who has made himself known to us in the clearest manner by his works. A number of flints were exhibited from the strata in question, which had apparently been intentionally chipped and exposed to fire. The general opinion of the savants assembled at Grenoble was that there can no longer be any doubt of

the existence in the tertiary period of an ancestral form of man.

Our neighbors at Antwerp opened an International Congress of physicians engaged in the cure of mental diseases, under the presidency of M. Victor Desguin, who is the president of the Belgian society for mental diseases. Among the members of the Congress are Messrs. Pritchard, Davies, and Eaves, of London, and Peacocke and Curtis from Ireland, with Dr. James Rutherford, of Scotland. In his reply to the burgomaster's speech of welcome, Dr. Desguin explained that the scope of the Congress comprised especially these two subjects: (1) the basis of a good international statistic concerning the mentally diseased; (2) the relations between criminality and mental disease. The Congress charged an international committee with the duty of determining the headings for the bases of statistics regarding mental disease. Prof. Lefebvre, of the University at Louvain, speaking on the first subject, said, after having stated that there were any number of classifications used by great men, that he was forced to admit that none of them fulfilled the duty needed. He proposed to base all future statistics on the *number* of patients in any place; the *cause* of their alienation, if it could be found out; the *kind;* next the *duration;* and, finally, the *termination*. M. Oudart read an interesting paper on "Colonization." It seems that in Belgium, as well as in other countries, the number of the mentally diseased is fast increasing. The well-known colonies of Gheel and Berghe were spoken of, and M. Oudart thought it was greatly preferable to develop the idea of colonization than to shut up the mentally afflicted. The advantage as regards economy was great, and the influence for cure was immense. M. Benedikt, of Vienna, made quite a remarkable communication on the therapeutic effects of static electricity. He believes that, administered in the form of a douche, static electricity is a powerful modificator of the intracranial circulation. It is in this way that he can explain the good results he has obtained in auricular disorders which accompany nervous affections. He reported several cases, even of mania, that were relieved in this way. He did not, however, claim as yet to cure his patients definitely, but certainly he obtained a most marked sedative effect. M. Verriest presented a hypnotic patient who offered a most curious example of *double existence*. About the age of fifteen, the girl, who had been a most quiet, reserved person, had an attack of convulsions, after which she became quite changed in character, but in this condition *she could not drink*. A second attack brought her back to her first mood; a third then returned her to the second state, and so on. Dr. Verriest could provoke either side of her character with a few passes over her eyes and a sudden shout. When in her first phase she cannot speak and does not know where she is, while she remains quiet and silent when spoken to; when water is offered she drinks several glasses, because when she goes into her second mood she cannot drink, but she becomes very gay and lively, smiling and talking. The latter part of the Congress was taken up with the discussion of the relations between criminality and insanity.

The Italian Medical Association held its eleventh General Congress at Perugia, Italy, during the early part of September. Prof. Madruzza was the President. Dr. Bianchi, of Florence, spoke of his way of obtaining the contour of an organ by having the patient or an assistant fix a Camman's stethoscope about the centre of it, while the physician puts the two tubes in his ears and proceeds by percussion, marking the points where the dull vibrations give place to strong ones. The same gentleman spoke of the therapeutics of the sap of the fig-tree. Pliny and others, writing in the Middle Ages, used it. A few drops extracted from the leaves and fruit, placed on a piece of wet fibrin, rapidly reduce it to a substance soluble in water, which gives the reaction of peptone. Signor Bianchi has found this substance very useful in dyspepsias where there was a deficiency of the gastric juice. It could also replace papaine in application to the diphtheritic membrane and to old ulcers. Dr. Pagliani reported a large number of cases of sciatica which he cured by the application of a revulsive in the shape of a cerate made with senna. This plaster was kept on the part for seven hours, and followed by baths of hot, dry air. Some twenty-one cases of cure were attested. Dr. Giacomini, of Turin, presented a large number of microscopical preparations kept by a new process which does away with glass slides and covers altogether. By this method a great economy is realized, and the preparations are easy to make and can be handled much better than glass slides. The microscopical section is placed in a stratum of gelatin and covered back and front with a layer of collodion, very thin, to protect and render unalterable the gelatin. They are prepared as follows: Commence by cleaning a glass slide of the size wanted; this is the capital point,—all impurities must disappear. This done, then pass over the glass slide a very thin coating of collodion and allow the ether to evaporate. Then plunge it into a solution of gelatin at ten per cent., at the temperature of 50° C. The section is applied to the collodioned glass, and afterwards it is taken out of the bath of gelatin. The whole is now allowed to dry, and it is then slipped off the slide, when a clear preparation is obtained that is as light as paper. Prof. Giacomini passed around a number of these preparations which were as large as an octavo sheet of paper, and which took in complete brain-sections that would

certainly be of great use in macroscopic as well as microscopic study. Dr. Manassei, of Rome, had a good deal to say regarding the employment of medicinal substances incorporated in soap, such as camphor, naphthol, carbonate of lime, sulphur, boric and salicylic acids, arsenic, and corrosive sublimate, which are all used now as medicinal soaps and are highly advantageous, as they do not soil linen so much and allow of more ready cleansing of parts to which they are applied. Friction with these soaps softens the skin and impregnates the epidermis with the virtues of the medicine employed. We have already spoken of making mercurial ointment with soap. The only question to solve is, What relation have the salts of soda and potash in the soaps to the medicinal substances employed?

Naturally enough, cholera is still on the *tapis* here, although the daily papers do not mention it at all. While there has been considerable amelioration, yet it must be confessed that the whole of the south of France, Italy, and most of Spain is still infected with the fearful disease. The total of last week at Marseilles was forty deaths; a few weeks ago it was more than that number per day. At Toulon the rate is about ten per day now. A large number of the towns along the south coast (even Nice) have several cases. In Spain it seems at last to take a favorable turn, and only several hundred cases are reported daily (deaths). In Italy, most of the places along the Mediterranean are infected more or less. About Naples and in that city itself it rages with considerable intensity. Palermo, in Sicily, has the epidemic in its worst form: more than a hundred cases a day in the city itself. This has caused the ignorant people of Naples and other ports to insist on all persons coming from Sicily being forced to return. Here in Paris, so far, there has been no cholera. A fright was caused by an outbreak of dysentery at one of the large barracks; but, on boiling all the water used, the epidemic passed away. Prof. Peter held the Académie de Médecine during three sessions while he exposed his theories and treatment of cholera. Last year he had some fifty cases to treat, and he gave the substance of his treatment in his lectures at the Medical School. He believes that cholera is the top, as it were, of a morbid series which may stop anywhere from a simple diarrhœa up to real cholera. *Cholera nostras* is only a form of Indian cholera, from which it differs in intensity: either of them may become epidemic. As to real cholera being contagious, the professor thinks that it is limited to persons who are weakened by disease or to some individual predisposition. Thinking that the disease is an irritation of the solar plexus, with a hyperæmia of the digestive tract, Dr. Peter recommends every possible means to combat this irritation: vesication of the epigastrium, continuous current,—one electrode on the stomach and the other in the rectum (a current of twenty-five milliampères was used),—dry frictions, alcohol; for pain, hypodermics of hydrochlorate of morphia; in plethoric persons, leeches; and, finally, Prof. Peter spoke at length of the use of Dr. Chapman's ice-bag. He had used it in ten cases, with a result of ten cures. The ice-bag is a triple rubber bag, about twenty to twenty-four inches in length and about four inches wide. Each part is filled with fine pieces of ice, and it is applied to the back along the spinal column. Its application should be constant, so the ice must be changed from time to time. The vomiting was stopped by its use almost at once, while there was a great diminution in the cramp. The patients warmed up, the pulse came back, and all the symptoms gradually went away. Dr. Chapman is an English physician who has practised now for a number of years in Paris, but was formerly in India, where he had cholera to treat. He has just published a book entitled "Cholera Curable." * Some of your readers may remember his former recommendations of the ice-bag for sea-sickness. Dr. Miquel, whose interesting work here in regard to atmospheric germs is so well known, has a late article on the subject of "Cholera and Atmospheric Bacteria," comparing the number of bacteria found in the air during the last epidemic and those before and after. It was seen that the number was greatly increased during the epidemic, and grew with it, falling afterwards. A series of tables are given to prove this fact. The more the air was charged with bacteria, the worse the cholera was; so that a microscopic analysis of the air leads to this hypothesis,—that Indian cholera has for its morbid agent a bacteria; that this bacteria can take as a vehicle the air, and so infect human organisms directly or by means of entering the water or food we use. Temperature does not seem to affect the air-bacteria. The conditions that preside over their generation are *heat* and *humidity;* those that favor their dissemination are *dryness* and *wind*.

A treatment of enteritis in children which was very successful last summer in France it may be well to give you in full, as the mortality to infants in America is even more than it is here. Some two hundred and fifty cases were treated in all, with a result of only two deaths, under the direction of Dr. Cayla. With an absolute milk-diet (with lime-water), starch-water rectal injections were given, and the two following prescriptions:

℞ Tinct. nucis vomicæ, gtt. iii;
Syrup. krameriæ, 15 grammes;
Syrup. cydonii, 15 grammes;
Aquæ destillatæ, 40 grammes. M.

* Cholera Curable. A Demonstration of the Causes, Non-Contagiousness, and Successful Treatment of the Disease. By John Chapman. 8vo. Pp. 144. London, J. & A. Churchill.

℞ Potassii bromidi, 50 centigrammes;
Syrup. belladonnæ, 15 grammes;
Syrup. menthæ pip., 15 grammes;
Aquæ destillatæ, 40 grammes. M.
Sig.—Teaspoonful hourly of each alternately.

The nux vomica increases the contractility of the muscular fibres, the rhatany and quince act as astringents, while the bromide and belladonna stop the exaggerated secretion of the glands.

While on formulas, it may be useful to give the injection used here in rectal alimentation in cases of cancer of the stomach:

Beef-soup (concentrated and all the fat removed), 200 grammes;
Extract of cinchona (aqueous), 1 grm;
Port wine, 20 grammes.
To be administered five times a day, per enema.

We close our letter with a favorite formula of Dr. Juliens for pruritus:

Pomade for Pruritus Vulvæ.

℞ Zinci oxidi, 25 grammes;
Acidi salicylici, 1 gramme;
Glycerini amyli, 25 grammes. M.
Sig.—Apply as needed.

THOMAS LINN, M.D.

PARIS, September 23, 1885.

BOSTON.

AN UNSATISFACTORY WATER-SUPPLY.

THE water-supply of Boston has engaged a large share of the attention of her citizens during the last few years, and more especially perhaps during the last months. Owing to methods of administration which seemed questionable to the public, the former Board of Water Commissioners has been retired and new men appointed, who have taken hold of the problems which confront them with a manifest desire to do their best towards their solution. As in most of the older cities, our water-supply has grown not from one comprehensive original plan, but by such additions as were rendered necessary and available by the circumstances of the hour. These additions, however, have reduced the quality of the water from one of the best to one of the poorest. The original supply was taken from Lake Cochituate, some twenty miles west of the city. This has been supplemented by other neighboring bodies of water. One of these is Farm Pond, some two or three miles west of Cochituate. The water from Sudbury River also, still farther to the north and west, is collected in basins, and carried into and through Farm Pond, to be added to our supply.

About two years ago a very offensive taste was perceptible in this water. Prof. Remsen, who was called in as an expert, declared it to be due to algæ decomposing in Farm Pond. A conduit was therefore begun to carry the water from the river through the basin of Farm Pond, without intermixture with the waters of the latter, should these remain unhealthy. The so-called "cucumber taste" is now not present to any degree in this water.

A second and quite independent source of supply is from the Mystic River, north of Boston. This was brought in as the dower of Charlestown when that municipality was annexed to Boston. It also supplies one or two other cities and towns contiguous to Charlestown, but not within the limits of Boston.

The great difficulty with our present supply is this, that it is obtained from sources which form the natural means of drainage of other communities, and have been so used for years. These communities naturally consider it a grievance that they should be obliged at their own expense to provide new means of drainage simply to secure the purity of water that other persons choose to drink. Many of the people of Natick are emptying their drains into Pegan Brook, a tributary of Lake Cochituate. Manufacturing establishments and private houses in Framingham drain into Beaver Dam Brook, another tributary. A junction railway station at the latter place, well supplied with water-closets for the large number of travellers who use the station, drains into a cesspool which overflows into Farm Pond. The State Woman's Prison at Sherburne has an expensive but not particularly successful system of irrigation by which the filtered sewage, retaining, however, a large amount of organic matter in suspension and solution, finds its way into the lake. It is obvious that a considerable portion of human excreta must get into the Cochituate system, and that if any cases of typhoid fever or cholera were to occur in the houses contiguous to these streams the most disastrous results might be expected among the citizens of Boston.

The Mystic system is contaminated by refuse more obnoxious to the visual, olfactory, and gustatory senses, but perhaps no more dangerous than the Cochituate supply. A large number of tanneries in the towns of Winchester and Woburn are situated in the Mystic basin. A sewer was built by the city of Boston a few years since for the protection of this water, but without the co-operation of these other towns, so that the sewer was made only large enough to receive the tannery waste. Now a number of these manufactories do not make use of the sewer at all. At some points on this source of supply one may, as the writer has done, scoop up handfuls of hair and decaying animal matter. It is now under contemplation to abandon the whole Mystic system, and this will have to be done, or else much more active steps must be taken to shut off these nauseous impurities. A decision in a test-case brought against a person for contaminating the supply has been favorable to

the complainants, and such cases in future may be referred directly to a judge without going before a jury, the latter being usually prejudiced in favor of the defendants. Still, legal steps have to be taken separately against each person guilty of contaminating the supply, and this of course takes time.

A committee appointed jointly from the two district societies (Suffolk and Norfolk), which comprise most of the physicians of the city, has during the past summer investigated the matter of the purity of the water-supply. They discovered nothing that was unknown before, but have done something in the way of calling public attention to these abuses. At the request of the mayor they made a report to him of their findings, which was by him transmitted to the Water Board. The latter body have since issued a full report, covering the whole matter of the water-supply, and detailing clearly its sources of contamination. It is expected that the legal department of the city will be invited to take energetic action in the early future.

Some two years ago a State Commission was appointed to investigate the disposal of sewage, with a view to relieving the river-basins and protecting the water-supply of the various portions of the State, so that no one community should imperil the health of any other. A report from this Commission to the Legislature is hoped for this winter or next, and some suggestions of practical value are looked for.

THE MONTREAL EPIDEMIC

of smallpox has caused some anxiety not only in the border States, but also in Massachusetts, on account of the large travel between Canada and Massachusetts, and because many French-Canadians, who by reason of their bigoted opposition to vaccination and to isolation are especial sufferers from the disease, are in the habit of coming into our manufacturing towns for work during the winter months. Realizing the inadequacy of any individual State Board of Health to prevent the importation of the disease, the Governors of several States joined in a request for aid from the medical officers of the Treasury Department. Accordingly, Surgeon Austin, of the Marine Hospital Service, has gone to Burlington, Vermont, where he receives reports from a corps of inspectors who watch all trains crossing the line, vaccinate all unprotected persons, and detain such individuals and luggage as have been exposed to the disease. The employés of the Boston and Lowell and other roads communicating with Canada have been vaccinated, and no through-cars are now run to Montreal, the passengers changing cars at or near the line. Suspected baggage is fumigated at Rouse's Point, St. Albans, Richford, Newport, and Island Pond.

A NEW NURSES' HOME.

At the City Hospital, where for several years a successful training-school for nurses has been in operation, the nurses have had quarters in the hospital buildings, in many cases not out of earshot of the patients, and in others in rooms which were originally intended for patients. Last year an appropriation of forty thousand dollars was made by the city government for a building to be used as dormitory and refectory for the nurses. This building has been completed, and is just occupied by the nurses, who a few nights ago received their friends in it. It is one hundred by thirty-eight feet, four stories high, and is a tasteful structure of brick, accommodating sixty-eight nurses. The three upper floors are taken up wholly by sleeping-rooms, most of them designed for single occupants. On the lower floor, beside a few sleeping-rooms are reception-rooms and parlors, some of which at certain times are used for lecture-rooms in connection with the work of the school. The floors throughout are finished in hard wood with plain mats. In the basement is the kitchen with its adjuncts. The building lies just across the street from the hospital, and takes the nurses out of doors in passing to and from their work. An enclosed yard will, it is hoped, prove capacious enough for one or more tennis-courts, wherein the nurses when off duty can throw off the depressing influences of the wards.

A NEW HOSPITAL

has just been completed under the plans of the Board of Directors for Public Institutions, on Deer Island in the harbor, where are some of our reformatory institutions. It is on the pavilion plan, is of wood, and contains three wards. It was inaugurated September 30 by the usual ceremonies in favor with junketing councilmen on such occasions, and was opened for patients October 1. C. F. W.

CHICAGO.

PROFESSORS and pupils are returning to their posts, the medical schools are again showing signs of activity, and the janitors and porters have assumed that air of importance and responsibility so well calculated to impress all first-course men. The classes promise to be quite as large as those of preceding years.

As it is becoming fashionable to have a hospital of some kind or other as an annex to the medical school, one of our institutions, not to be outdone, has devoted a part of the college-building to hospital purposes, beds having been put in, and one or two wards opened for the reception of patients. This is of course very handy, but it is a question (for obvious reasons) if it be wise. This may be entertaining to the students, but its effect on patients remains to be seen.

The committee of the City Council is having its periodical struggle with the sewage question. Meantime, the filth for the mos

part goes to the lake, and though it may not yet have contaminated our drinking-water, such a condition can be postponed for a few months at most, and it is altogether likely that the city authorities (who, by the way, are totally incompetent) will wrangle and argue valuable time away to no better purpose than the expression of Common Council sense and wit.

There has been another revolution in our county insane asylum. Dr. Kiernan, after a long struggle with the rough element constituting the employés, and after enduring repeated personal assaults, had to succumb, and his resignation was eagerly accepted. The old order of things is again operative, and the "gang" is in full possession.

The only hope for all State and county institutions for the insane is to take them out of politics. As it is now, they serve but one purpose, that of providing places for men who could not outside the institution earn half the compensation.

The question of the intestine differences regarding the meeting of the International Congress hardly disturbs professional equanimity, the balance being rather favorable to the action of the American Association. The homœopaths of this city have raised a feeble cry for some representation, arguing that if leading regulars of this city can consult with them, the said regulars must in so doing recognize their methods, and therefore they stand upon a common basis.

A prominent homœopath remarked, "Do you think that when I meet an 'allopath' I am going to remain a passive witness and obedient tool to the dictates of one who I know takes no stock in my methods? No, sir; I invariably see to it that he meets me at least half-way; and I could name more than one prominent man who has given as substantial support to the theories of Hahnemann as I could wish. If representative men of your school can meet us and recognize and approve our methods, why can they not accord us recognition in their councils?"

Is it different that two should meet in council, or that twenty should?

Typhoid fever has been prevailing to some considerable extent, but is in most cases of a mild type. The past summer has been unusually cool, diminishing our mortality in certain directions.

CHICAGO, September 29, 1885.

HEMORRHAGE FROM A TOOTH-SOCKET.—Dr. Blackville reports a case of hæmophilia in which obstinate bleeding followed the extraction of a tooth. Ergot and witchhazel were given internally, and Monsel's solution applied locally, without checking the hemorrhage, when it occurred to him to fill the alveolar cavity with dry plaster of Paris, a few repetitions of which completely controlled the flow.—*Med. and Surg. Reporter.*

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, SEPTEMBER 10, 1885.

DR. J. HENRY C. SIMES, Vice-President, in the chair.

DR. GEORGE DOCK exhibited to the Society a patient suffering with

SECONDARY EPITHELIOMA,

and related the following history:

The case occurred in the practice of Dr. W. W. Keen at St. Mary's Hospital, to whom Dr. Dock acknowledges his indebtedness for the opportunity of recording it.

Mary C., æt. 70 years, married, born in Ireland, applied for treatment November 29, 1884. Her personal and family histories seemed to be unusually good. No traces of constitutional disease can be found. She uses alcoholic liquors in moderation, and has smoked a clay pipe for the greater part of her life. Filling the right submaxillary region and extending up over the inferior maxilla was a tumor, the distinct outlines of which included a space about three inches in diameter. The lower part was very prominent, standing out as a flattened node one and a half inches in diameter and about three-fourths of an inch high, the whole height of the tumor being one and a half inches. The growth was hard, immovable on the lower jaw; the surface was smooth and red, changing to a dull purple on the nodular elevation. On the summit of this growth was an opening leading upward and inward three-quarters of an inch. The skin around the opening was everted, and the surface of the crater-like cavity covered with large and small granulations, which exuded a thin, gray, offensive pus. The neighboring lymph-glands were not enlarged. The general condition was good.

The patient stated that the growth first appeared six months before admission to the hospital as a "kernel" below the jaw. She applied various poultices and salves to it. The tumor grew rapidly for the following four months, when it opened, discharging a large amount of pus; after that there was no apparent increase in size. The patient could assign no cause for the tumor except a scald received about one year before on the lower lip, near the angle of the mouth on the right side. This was followed by an ulcer, which was removed at the Episcopal Hospital in February, 1884, about two months before the appearance of the enlarged gland. Dr. J. M. Bradford, late resident-physician at the Episcopal Hospital, states that the ulcer was noted as epithelioma.

On December 3, 1884, Dr. Keen removed the tumor, together with a margin of healthy

skin and the submaxillary salivary gland. The external plate of the inferior maxillary appeared roughened, and was cut away. The cavity of the mouth was not opened. By the use of hare-lip pins and sutures the edges of the large wound, four and a half inches in diameter, were approximated almost perfectly. The dressings at first were carbolized; afterwards iodoform was used. In the fourth week after the operation a small, red, indurated, sometimes painful, spot appeared in the skin just posterior to the wound; a few days later the patient was discharged.

Microscopic sections made through various parts of the growth showed the structure of squamous epithelioma everywhere. The salivary gland was invaded. No trace of the lymph-gland could be found, and the supposition was that it had ulcerated away completely.

The patient was lost sight of until the beginning of May, 1885. She stated that, after leaving the hospital, the small swelling alluded to increased rapidly in size, and in a few weeks was larger than the one removed. She used no irritating measures, but the tumor broke down and ulcerated away, leaving a large granulating surface.

On examination, I found an ulcer on the side of the neck, extending from one inch to the right of the median line to beyond the angle of the jaw, irregularly circular in outline and containing islands of epithelioma. There was a small opening into the cavity of the mouth midway between the angle and the symphysis of the jaw, and just inside of the inferior border of that bone. The symphysis was drawn to the right about half an inch. There was a hard, tender swelling on the gum, above the inner edge of the opening, covered with small, dark-red nodules. In June the inferior maxilla was still more atrophied, and had separated at the point of swelling and opening before mentioned. The adjacent ends of bone and gum were covered with a small fungous growth.

The process of atrophy and new growth is still continuing. The left alveolar process approaches the median line of the oral cavity, and the point of the chin is on a line dropped from the outer angle of the right eye. The ulcer on the neck is healing, but the new growth in the mouth is rapidly enlarging, so that the tongue cannot be extruded. There are no enlarged lymph-glands, but within a few days the patient has complained of pain in a gland in the subclavian region. The general condition is very poor; the patient lives on liquid food, and takes morphia to induce sleep.

[The patient and the microscopic sections were then examined by the members of the Society.]

Dr. T. D. DUNN exhibited the contents of a cyst recently removed from the back of a cow.

Dr. GUY HINSDALE exhibited a specimen of

ENLARGED PROSTATE.

The specimen had recently been presented to the Mütter Museum of the College of Physicians by Dr. J. L. Stewart, of Erie, Pennsylvania, and was removed from a man, æt. 75 years, who, sixteen years previously, had first come under Dr. Stewart's observation. At that time he was a strong, well-developed man, who had never been sick before in his life, but was then suffering from retention of urine, which had existed for seventy-two hours. It was found to be impossible to introduce a catheter, owing to an enlarged prostate, estimated to be larger than a hen's egg. Circumstances rendered it necessary to force an instrument through the gland, and five and a half pounds of urine were drawn off. A train of most unpleasant symptoms followed, and for weeks there was profuse suppuration, with complete incontinence and great prostration. After about thirty days, improvement began, and continued to complete recovery. Three months afterwards the patient seemed perfectly well.

Attacks of cystitis and retention became frequent, and for sixteen years only once did an interval of over three months pass without an attack, the usual time being about twenty days. During this time Dr. Stewart introduced the catheter eleven hundred and ninety-four times. Pain was intense during the later years, when four or five ounces of urine had collected in the bladder. Meantime, the prostate continued to increase in size, and in November, 1884, was believed to be of the size of a large orange. On the night of the 27th of May, 1885, the patient had his last attack. Dr. Stewart not being at hand, two other physicians did not succeed in introducing an instrument. Just before 9 A.M. of the following day the man was attacked with the most excruciating pain, followed by a severe chill. At this time it is believed by his medical attendants that rupture of the bladder occurred, and the early date of this accident is accounted for as being the result of the contracted condition of the bladder. From this time there was no acute pain, but a severe aching followed by prostration. At 9.30 A.M. the bladder was aspirated, one ounce of urine coming away. Dr. Stewart catheterized him on the third day, drawing about a tablespoonful of urine. The patient died on the morning of the fourth day. His mind was clear and his voice strong to the last.

The post-mortem examination was not made by Dr. Stewart personally. It is stated that there was a rupture of the anterior part of the bladder, near the fundus, and that the cavity of the abdomen was filled with urine.

The specimens were not removed in such a way as to make this evident.

The specimen, as presented, consists of the prostate gland laid open by a cut in the ver-

tical line, and having attached to it the bladder, the walls of which have been cut in several directions. These walls are thick, and have apparently undergone fatty degeneration, as had also the kidneys, which accompanied the specimen, the pelves of which were thickly overlaid with fat. The long diameter of the prostate, after being in alcohol for three months, is three inches; the shorter diameter, two and three-quarter inches; the third lobe is one inch long, and through it the catheter passed and still remains in position. The bladder-walls, when replaced, indicate a very small internal capacity.

Dr. J. M. BARTON stated that but one case of rupture of the bladder from over-distention had come under his observation. It occurred in a German, who had an impermeable stricture of eight years' duration. No urine whatever passed. The contents of the bladder were removed several times by aspiration, while attempts were being made by filiform and other bougies to pass the stricture. As these failed, perineal section was suggested to the patient and his friends, but refused, and the doctor was told that they would send for him when they needed him. Three days later Dr. Barton was sent for. He proceeded to the house, accompanied by Dr. S. W. Gross. The man was in a dying condition: the bladder-tumor, which before was very prominent, had disappeared. Aspiration over the pubes and a trocar inserted by way of the rectum both failed to reach any urine.

On post-mortem examination, a small rent was found in the upper part of the bladder, but the specimen could not be secured.

In old cases of prostatic obstruction Dr. Barton had several times found, on post-mortem examination, that the patient had thrust the instrument through the "third" lobe. In one case several such openings had been made and had healed kindly.

The Committee on Morbid Growths reported regarding Dr. Mitchell's specimen of

CANCER OF THE STOMACH,

exhibited at the last meeting in June, as follows:

(*a*) *Stomach.*—Microscopic sections across the wall of the stomach show an active proliferation of the epithelium of the mucous membrane pushing its way into the wall, infiltrating it and forming alveolar spaces. The wall is further infiltrated with young cells, which for the most part replace the normal structure of the part. The process has probably been a chronic catarrh, with great hypertrophy, passing gradually into a carcinomatous type.

(*b*) *Omental Nodules.*—Sections of these show an indistinct alveolar structure filled with epithelial cells, and a small-celled infiltration of the adipose tissue. The appearances are those of a carcinoma, secondary probably to the growth in the stomach.

The committee reported regarding Dr. Nancrede's specimen of

HÆMATOCELE OF THE TESTICLE

as follows:

Sections exhibit layers of more or less well developed connective tissue, through which are scattered numerous young connective-tissue cells. No evidence of sarcoma-tissue is present. The growth should be classed as a chronic connective-tissue hypertrophy, and, as the sac contained hæmatin, the specimen is of chronic hæmatocele.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held October 1, 1885, the President, A. JACOBI, M.D., in the chair.

ADDRESS BY THE PRESIDENT.

In his address the President called attention to a few facts which were likely to have an important bearing upon medical progress. He first referred to the collective investigation of disease, and the work proposed to be done in this direction by the committee appointed at the International Medical Congress held in Copenhagen. After stating the objects to be accomplished, and refuting objections which had been made to collective investigation of disease, he expressed the hope that the Committee would be sustained in its efforts by the general profession. He then compared the code of ethics of the Medical Society of the State of New York with those of the American Medical Association, as interpreted at the recent meeting in New Orleans, and expressed the opinion that there was but little difference between the two as it concerned consultations. The State Society, therefore, was to be congratulated upon the influence which its action had had in bringing about in so short a time this change of opinion on the part of the profession throughout the country. But as he had replied to a suggestion by one of the members of the Academy, this Society was not the place to introduce the subject of medical politics. He then spoke of amendments to the by-laws, and suggested the importance of widening the duties of the Committee on Ethics, requiring its members to bring charges against those who violated the rules, and not to wait until charges were preferred by another before they took action.

Another warning was given to those who sought advertisement in public prints.

OBSCURE CASES OF WEAK HEART.

Dr. R. VAN SANTVOORD then read a paper on this subject. The histories of four cases were related, which were made the basis of remarks upon special symptoms and upon treatment, particularly by digitalis and caffeine. Weakness of the heart-muscle, independent of valvular lesions, is known to be

an important factor in a large number of morbid conditions; it is the chief source of danger in most acute febrile diseases; it occurs as a result of long-continued anæmia and of various toxic conditions, particularly in alcoholism. Failure of cardiac compensation is frequently the cause of death in chronic renal disease. The right ventricle is frequently affected in obstruction to the lesser circulation. Degeneration of the cardiac muscle might result from inflammation in the course of general diseases, or as a result of lesions of the coronary vessels. The heart might be weakened by repeated strain, and at the autopsy we might find fatty, granular, or waxy degeneration, or the structure of the heart might appear normal, although the history during life pointed to cardiac failure. The diagnosis in many of these conditions could be easily made, but in others the relation of the symptoms to cardiac failure might be overlooked. It was to these obscure cases that the author directed attention.

In the first of the cases which he reported the patient was a man, 42 years of age, with a tendency to corpulency. He had the appearance of being in robust health, but he complained of falling asleep during the day, of headache, and weak memory. He was not addicted to alcohol in excess. There was some indigestion and very slight dyspnœa. The heart-sounds, especially the first, were weak; there was reduplication of the second sound at the base; the pulse 75. Dr. Van Santvoord made the diagnosis of weak heart following pneumonia, a severe attack of which the patient had two years before, at which time his symptoms began. At first the tincture of digitalis and tincture of nux vomica were given, but without improvement, when caffeine and strychnine were substituted, with the result of soon increasing the heart-sounds and causing the disagreeable symptoms to disappear. Twenty-three weeks after the commencement of treatment the patient was in a comfortable condition. There was some shortness of breath, and reduplication of the second sound of the heart could still be heard at the end of inspiration and commencement of expiration.

The second case occurred in a stock-broker, aged 38, who had had business trouble which led him to excessive drink and to take but little nourishment. There was a family history of gout, and one relative had had asthma. Dr. Van Santvoord found slight dyspnœa at the time he was called; the lungs were normal; the first heart-sound was weak, the second hard and metallic and not quite clear. The urine contained a small amount of albumen, with a specific gravity of 1.024. The patient managed to refrain from alcohol, was given good food, and morphine and Hoffman's anodyne at night, and within six days great improvement had taken place. The amount of urine passed during the twenty-four hours was one quart, the specific gravity being 1.014; no albumen. The symptoms, however, returned as soon as the doctor's instructions could not be fully obeyed. The apex-beat was weak, the pulse 102, with occasional shooting pains from the apex to the scapula. Remedies were administered for the correction of the condition of the alimentary tract, and digitalis for the cardiac weakness. Within two days the pulse fell to 84 and increased in tension. After six months' restraint from alcohol, the patient's condition was comfortable and his general health much improved. The first heart-sound was still short and valvular, the second metallic and sharp, the arterial tension low, the pulse 82. The urine contained a small amount of albumen and a considerable number of hyaline casts. Malnutrition had existed in all the organs, resulting from wrong habits, but the rapid and continued improvement after the use of digitalis was proof that the heart was the organ chiefly affected. The exact cardiac lesion was conjectural; there was persistent irritability of the heart, apparently due to mental worry. It was fair to conclude, from the entire history, that the albuminuria was probably unassociated with grave organic changes in the kidneys.

In the third case the patient, aged 54 years, had been accustomed to out-of-door sports, and had probably over-exerted himself; but his health had previously been good, except for constipation. When Dr. Van Santvoord saw him he complained of drowsiness, lassitude, inaptitude for work, and distressing headache, chiefly in the vertex. He had long been in the habit of rising at night to urinate. The apex-beat was found in the line of the nipple, sixth intercostal space, where there was a faint systolic murmur; the cardiac sounds were weak; the lungs were normal. A stomachic failed to correct the symptoms in the head. The tendency to constipation responded only to faradization. After twelve days' administration of ten minims of the tincture of digitalis and twenty minims of the tincture of chloride of iron, the heart-sounds had become louder, the pulse stronger, and the general condition markedly improved. The urine was still passed in large quantity, specific gravity 1.010 to 1.019; no albumen. It was learned that the patient had been treated for stricture, and was suffering from seminal emissions. The enlargement of the heart and the passage of a large quantity of urine led to the suspicion of contracted kidney, with secondary heart-failure, although against this view was the fact that the specific gravity of the urine was normal when the amount passed was considered, and it contained no albumen. The patient went South, and remained in fair health. A year afterwards he visited Dr. Van Santvoord, when he was a little short of breath; had an indefinite disagreeable sensation in the head, and occasional shooting

pains in the arms and legs; the apex of the heart in its former situation; the heart-sounds (especially the second) weak, with a reduplication of the first to the left of the sternum and on a level with the fourth rib. The sphygmographic tracing was of large amplitude, the tidal wave more marked, the aortic notch much higher in the tracing, and the dicrotic wave far less developed, than in the case of the second patient; the pulse 75. Digitalis and fluid extract of ergot caused within ten days diminution in the amplitude of the pulse, lessening of the dicrotic wave, and lowering of the pulse to 64. The sphygmographic tracing now differed from a healthy tracing only in a little lower tension. The urine had a specific gravity of 1.015; no albumen; few pus- and red blood-globules; seventy ounces in the twenty-four hours. The fact that the patient had held his own for a year, the specific gravity of the urine normal for the amount passed, and that the sphygmographic tracing showed low arterial tension, led to the conclusion that the polyuria was due to some other cause than contracted kidney, being possibly a reflex result of the urethral lesion. The cardiac failure, therefore, seemed to be an independent matter. The age of the patient pointed to an early stage of one of the chronic degenerative processes. His addiction to athletic sports suggested the weak, dilated heart, without recognizable histological change, noticed by Münziner.

The fourth case was introduced only on account of certain special features. A boy, aged 14, had a severe attack of measles; previously health had been good. After convalescence he suffered from dyspnœa and lancinating pain in the cardiac region on running. He was thin and pale; cardiac beat was marked over the apex, in the epigastrium, and second left interspace; both ventricular areas enlarged; the heart-sounds loud. There was distinct reduplication of the second sound in the third left interspace, near the sternum. A loud, blowing, systolic murmur was heard over arteries at base of the neck, transmitted into the brachials and femorals. Improvement took place under iron, strychnine, and rest. Dilatation of the heart diminished, the arterial murmur disappeared, the venous hum became lessened, but the reduplication of the second sound persisted. The absence of cardiac murmur and the rapid improvement pointed to cardiac dilatation, with perhaps some fatty degeneration.

It would be seen that reduplication of one or other of the heart-sounds was present in three of these cases. Different explanations of this phenomenon had been offered, but Dr. Van Santvoord thought the most probable one was that reduplication of the first sound was due to asynchronism in the contraction of the ventricles, and that reduplication of the second sound was caused by asynchronism in the closure of the aortic and pulmonary semilunar valves. Such was the explanation accepted by Bramwell for at least the large majority of the cases. The author then considered the theoretical speculations concerning this phenomenon by different writers, and said that persistent reduplication of the first sound had been clinically associated with functional disturbances and grave organic changes of the heart, with or without valvular disease, in a large number of cases; and we could at least say that its presence in any given cases was presumptive evidence of cardiac lesion, the character and gravity of which could only be determined by a study of the other symptoms. Reduplication of the second sound might be due either to derangement of the nerve-supply or lesions of the cardiac muscular fibres, causing contraction of one ventricle to take place a little more quickly than that of the other, or changes in the relative amount of resistance to be overcome by the respective ventricles. Clinical observation showed that reduplication of the second sound was so frequently associated with obstruction to the greater or lesser circulation, or with lesions of the cardiac muscle, or with a combination of both, that its presence should lead us to search for important cardiac disease.

In interpreting the meaning of a strong or a weak heart-sound, we should consider both the degree of arterial tension and the form of the ventricular contraction. The sphygmographic tracings exhibited in these cases showed that in a study of the weak valvular first sound the peripheral resistance to the circulation was as important an element as was the strength of the ventricular contractions.

Dr. Van Santvoord thought it probable that the contrasted effect of caffeine and digitalis in these cases was due to the slighter influence of caffeine upon the vaso-motor apparatus. Caffeine, it would be seen, had proved efficacious in some of the cases where digitalis had failed. The greater safety and more rapid action of caffeine would cause it to be preferred in cases of heart-failure occurring in acute diseases or primary degenerative process of the heart-muscle. He gave it in small but increasing doses, and preferred the combinations with salicylate or benzoate of sodium to the insoluble and unstable citrate.

In concluding his paper the author said that he had probably advanced no new truths, but he hoped it might have the effect of calling more general attention to this rather neglected class of cases of cardiac affections.

DISCUSSION.

Dr. JOHN C. PETERS related the case of a man, 60 years of age, who had always been healthy, of good habits, but who probably had become somewhat reduced in strength by innutrition. He then contracted bronchi-

tis, slight œdema of the lungs occurred, and what astonished Dr. Peters was the fact that there was great weakness of the pulse and cardiac failure. There was a struggle for life during ten or twelve days, after which convalescence slowly set in, and the man was now able to walk a mile. But the dilatation of the right side of the heart would probably not be restored for months. He felt sure that it had not existed before this attack.

Dr. L. WEBER used the hydrobromate of caffeine, and thought that it hastened recovery after weakness of the heart following acute diseases, as typhoid fever, pneumonia, scarlet fever. He would not use tincture of digitalis, but preferred the purer article, consisting of an infusion of the English leaves, or Squibb's fluid extract. In the greatly corpulent person, suffering from dyspnœa and apparently weak heart, he did not give drugs, but regulated the diet, restricted the use of liquids, and directed the patient to walk up-hill.

Dr. E. D. HUDSON said a differential diagnosis in cardiac affections could probably be arrived at if we studied carefully the anatomical structure of the organ, its nerve-supply, and the influence of disturbances of other organs upon the heart's action. First exclude valvular and organic lesions, and then the influence of excitement, depressed vital action of other organs, etc. A patient with a very slow pulse and cardiac symptoms without evidence of organic lesion, and suffering from constipation, would often be relieved of his cardiac symptoms by a cathartic.

The paper was further discussed by Dr. GARRISH and Dr. A. H. SMITH, who thought digitalis might have a twofold action,—viz., in large doses increasing the heart's action, and in small doses improving its nutrition; also by Dr. FRUITNIGHT and the author.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, SEPTEMBER 28, 1885.

The President, DANIEL LEWIS, M.D., in the chair.

AMONG those nominated to office for the approaching year were: Daniel Lewis, M.D., for President; Lawrence Johnson, M.D., for Vice-President; Wesley M. Carpenter, M.D., for Secretary; O. B. Douglass, M.D., for Treasurer.

GONORRHŒA IN WOMEN.

Dr. A. F. CURRIER read a paper with this title, and referred for a more complete exposition of his views to an article which he published in the *New York Medical Journal* for January 10 and 24, 1885. The author considered gonorrhœa to be more common among women in this country than was generally supposed even by physicians, and the many evil consequences of the disease made it of the greatest importance that it receive due attention. After quoting the conclusions arrived at in the article referred to, the author said that no important contribution to this subject had been made in American literature since Dr. Noeggerath published his paper in 1876, which had been previously published in Europe in 1872. The views which Noeggerath then advanced were received with incredulity both here and abroad, but they were now beginning to bear fruit, as had been predicted by their author. Dr. Currier then devoted a large portion of his time to a review of the parasitic theory concerning the etiology of the disease. Recent studies going to prove the causative relation of the gonococcus to gonorrhœa, especially those by German bacteriologists, were fully considered. The presence of this germ in any given case brought before the courts of law would offer important evidence. As to the parts liable to be affected by the gonorrhœal poison, Dr. Currier expressed the opinion that the urethra was less likely to be affected than had been stated. Its presence in the periurethral or præurethral glands was liable to be overlooked. Regarding the treatment for gonorrhœal affections of the tubes and ovaries, he thought that all means should be adopted for relief before resorting to abdominal section. The most common form of gonorrhœal disease of the Fallopian tubes is pyosalpinx; but pyosalpinx is not always of gonorrhœal origin. He had never seen gonorrhœa cause miscarriage when it occurred during the pregnant state; nor had he known it to produce any of the ill effects upon the offspring which syphilis is liable to do.

Regarding treatment, Dr. Currier was impressed with the importance of judicious prophylaxis, and thought that institutions which were liable to spread the infection should be under police regulation. Yet he had no elaborate plan to suggest, but simply referred to the government control over prostitutes in France, Alexandria, etc.

With regard to the local treatment, he reviewed the experiments of Oppenheimer and others as to the destructive effect of different agents upon the gonococcus, such as solution of corrosive sublimate, nitrate of silver, iodine, nitric acid, etc.; but for use in the prevention of the development of gonorrhœal inflammation after exposure, these agents were dangerous in the hands of persons ignorant of their proper use. The liability of infection could not be considered as having passed so long as any gonococci existed in the discharges. Experiments showed that cubebs and copaiba were harmless to the gonococci, but that, after having been ingested and eliminated by the kidneys, they were very destructive of these germs. Oppenheimer placed a solution of corrosive sublimate at the head of the list of gonococcides, but Dr. Currier had not found it satisfactory.

He had obtained the best results from subnitrate of bismuth in glycerin. They produced depletion of the congested tissue, and also acted as constringents. It was of the greatest importance that the treatment be carried out systematically, even in detail. The fourchette, glands, and crypts which were difficult to reach should receive particular attention. Dr. Currier thought gonorrhœa was absolutely curable. If the conditions of treatment pointed out were fulfilled, the dead germs would not reproduce themselves. Of course, reinfection was always possible.

Dr. H. T. HANKS said that the question of etiology was still a mooted one, but the pathological results of the disease were only too evident. He believed that a large percentage of all the special female diseases we were called upon to treat were the result of gonorrhœa. This was especially evident in dispensary practice. Dr. Hanks also believed that no doctor could make a positive diagnosis of gonorrhœa or state that it was absent in houses of prostitution unless it were by the aid of the microscope. Women whom the physician would pronounce free from gonorrhœa would be found to spread the disease. Dr. Hanks thought that gonorrhœal urethritis was far more frequent than gonorrhœal endometritis. He had confidence in the successful treatment of the disease, and thought that laparotomy should not be resorted to until every other means had been first tried and failed. He had found various solutions injected into the vagina, the injections made frequently and thoroughly, efficient in the acute stage of the disease.

Dr. H. J. GARRIGUES had made no observations regarding gonococci, but he was in the habit of differentiating between simple vaginitis and gonorrhœal vaginitis by the virulence of the inflammation in the latter affection. The disease was liable to affect the Bartholin glands, and in this case they should be opened and an application made. He had found the bichloride injection the most effectual, but he had formerly made use of other agents and they had proved satisfactory. He agreed with Dr. Currier that the urethra was not often affected. In disease of the uterus he used a strong solution of iodine. As to the efficiency of pads, he thought it was due chiefly to the glycerin itself rather than to the agent it held in suspension.

Dr. H. J. BOLDT found the urethra affected more frequently than the remarks of the other gentlemen would lead us to suppose. He employed chiefly iodine and glycerin, and glycerin and boracic acid. Most cases continued as long as three months.

Dr. LITTLE could not see how the discovery of the gonococcus was going to prove of much value in diagnosis among physicians generally.

Dr. MESSENGER did not think a patient could properly syringe herself; it should always be done by the physician, fully ballooning the vagina. This was easily effected by a syringe which he described. Bichloride of mercury was the best agent.

Dr. CURRIER, in closing the discussion, was not sure but that glycerin played an important part in the cure. He thought we had gained something in the way of diagnosis if it could be made by the microscope in cases of law, although it were not practicable in every-day cases.

THE TREATMENT OF LEPROSY.

Dr. H. G. FOX read the paper, which included an earnest plea for improving the leprosy patient's morale. He thought the medicinal treatment was often rendered ineffectual by excluding the patient from society, perhaps putting him in confinement, and by giving him to understand that his disease was necessarily fatal. He related the case of a missionary to the Sandwich Islands who acquired leprosy, and, notwithstanding the disease was well marked, the symptoms had nearly disappeared under moral influences and the use of chaulmugra oil. Dr. Fox also mentioned the question of contagiousness of leprosy and its hereditability. He did not consider it hereditary, and believed it to be very slightly contagious. He knew of no instance where it had gained a foothold in a civilized or refined community.

Dr. FULLER had seen several hundred persons affected with leprosy in Havana, where the disease was recognized as contagious, but only slightly so. They were considered incurable; their condition was low.

Dr. O. J. MOORE had seen the leprosy patients in the West Indies, and said that, so far as moral influence was concerned in the treatment, the buoyancy of the feelings in these patients was often remarkable. They were allowed many privileges, and could be seen in the streets. He thought the disease might in some cases be hereditary, although it was liable to pass over a generation or more.

Dr. J. C. PETERS had seen the patients with leprosy in Havana, and said they seemed indifferent to their fate.

Dr. DELAVAN spoke of a visit among lepers in Norway, where their number had been reduced from over three thousand to seventeen hundred. They had good surroundings and excellent asylum; were allowed considerable freedom. Their disease, however, was considered incurable, and they received little or no treatment. He was surprised at the author's expressions of hope for these patients. Most of them were of the lowest condition in life.

Dr. H. G. PIFFARD alternated the treatment between nux vomica and chaulmugra oil, according as the patient could bear it. Improvement was common under this treatment.

After some business transactions, the Society adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, SEPTEMBER 23, 1885.

The President, JOHN A. WYETH, M.D., in the chair.

RECURRENT EPITHELIOMA OF THE PENIS.

DR. W. P. WATSON presented a portion of the penis of a man 49 years of age, the seat of epithelioma. The man's family history was good; his health had always been good; there was absolutely no specific history. Dr. Watson was called to see him about two years ago, when he was having a profuse hemorrhage from the penis. The hemorrhage had occurred pretty constantly during the past year. In 1865, according to the patient's story, he received a slight wound on the dorsum of the penis, which bled, but did not require the presence of a physician. A short time afterward he entered Bellevue Hospital, where Dr. Hamilton cut away the foreskin for tight phimosis, and, as the patient stated, also removed indurated tissue; but this probably was only blood-clot. None of the head of the penis was removed. About six months afterwards a wart-like growth appeared on the under surface of the organ near the frænum, which caused irritation and was removed. Six months later an ulcerative process began at the base of this growth and spread, and, as said, finally caused almost constant hemorrhage and led to amputation by Dr. Watson two years ago. There had been no enlargement of the inguinal glands; the epitrochlear glands were slightly enlarged. The patient made a rapid recovery from the operation, and was now in good health.

The PRESIDENT said that during the past eighteen months he had seen four cases of epithelioma of the penis, in three of which he performed amputation. In all of the cases there had been phimosis. On inquiry among his friends, he could not learn of a single case of carcinoma of the penis in which phimosis had not existed. This certainly was another indication for circumcision.

VERMIFORM APPENDIX OF GREAT LENGTH.

Dr. LOUIS WALDSTEIN presented a vermiform appendix sixteen centimetres in length, which he had found in a dissection-subject at the German Hospital. Another interesting fact was that the appendix lay with the long axis of the body, and was attached to the hepatic flexure of the colon. There probably had been slight local peritonitis, dislocation of the colon downward, during which the appendix became agglutinated, and was lifted with the subsequent replacement of the colon.

RENAL AND BILIARY CALCULI.

Dr. WALDSTEIN also presented a urinary calculus composed of urates, which was interesting when taken in connection with the history. He was called to see the patient in April last, when he was suffering from an attack of colic, located in and just to the right of the epigastrium, extending over the abdomen. There was slight jaundice. The presence of biliary concretions, afterwards found in the fæces, confirmed the diagnosis of biliary calculus. Improvement took place under the Carlsbad treatment. But in June he was called to another attack: this time the pain commencing in the right lumbar region, extending down the ureter and right leg, and diffused over the abdomen. The subsequent passage of the calculus presented with the urine confirmed the diagnosis of renal calculi. The attacks were accompanied by pain in the glans penis, a dizzy sensation, and, what was peculiar, a tingling in the fingers of both hands. The patient had been a sufferer from digestive derangement for eleven or twelve years, and Dr. Waldstein remarked that such patients were liable sooner or later to suffer from biliary or renal concretions.

The Society adjourned.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

(Continued from page 34.)

The President, B. F. BAER, M.D., in the chair.

DR. E. E. MONTGOMERY read the following supplement to his paper on

BROMIDE OF ETHYL.

I read a paper on bromide of ethyl as an anæsthetic in labor before the April meeting of this Society. Although I did not attempt a history of the early administration of the drug, subsequent investigation has shown me that I did Dr. L. Turnbull injustice in not mentioning that to him we are indebted for the revival of this agent and its first use in this country. In following the German literature by which I was led to use this drug in labor, I ascribed its first obstetrical use to Lebert, of Paris. The first case in which he used it was for the application of forceps, and occurred in March, 1881; but a paper published by Dr. Turnbull (*Med. Bull.*, June, 1880) shows that he had then used it in a second case of labor and spoken in high terms of its peculiar advantages. Dr. H. Augustus Wilson had used it in labor prior to August 7, 1880, when he published an article upon this drug (*Med. and Surg. Rep.*, August 7, 1880). It becomes quite evident that the first obstetrical trial of this agent was made in this city, and the priority lies between the gentlemen named. Various mixtures of the ethyl have been advocated in labor and in minor surgical operations. Booth, of Ohio (*Ther. Gaz.*, 1884–85, p. 159), recommends alcohol, two parts; chloroform and bromide of ethyl, each one part.

W. A. Byrd, Quincy, Illinois (*Ther. Gaz.*,

March, 1884), has used bromide of ethyl, one part, chloroform, three parts, alcohol, four parts, in some ninety-eight cases, without a single unpleasant symptom. It has not everywhere received the same condemnation that is shown by the hesitancy to use it in this city. In spite of the bad name given it by two deaths under its use and the apparently dangerous symptoms induced by experiments upon the lower animals, its use has been revived by Chisolm (*Maryland Med. Journal*, 1882–83, ix. 388) and Prince (*St. Louis Med. and Surg. Journal*, 1883, xiv. 297), who strongly urge its use in minor operations and preliminary to the administration of ether. The last-named has reported five hundred cases in which it was used without a single unpleasant symptom.

A leading article in the *Therapeutic Gazette*, June, 1885, advocates a redistillation of a mixture of bromide of ethyl and olive oil as a valuable and safe antiseptic in labor. These facts are referred to simply to induce the profession to give this anæsthetic a fair trial in ameliorating the terrible suffering of natural labor.

Dr. MONTGOMERY exhibited a

UTERINE FIBROID POLYPUS.

Miss R., æt. 38 years, began to menstruate at seventeen years. The flow was regular, quite free, lasting a week, and was attended with pain the first three days. Ten years ago she had a hemorrhage, and subsequently several such attacks. Two years later she had a severe hemorrhage, followed by a bloody discharge continuing several months, since which time she has never been regular. The flow would occur too frequently, be very profuse, and attended with pain and loss of flesh. The symptoms were more marked during the last year. At one of the hospital clinics some years ago, the difficulty was ascribed to anteversion of the womb. Dr. Bournonville examined her three weeks ago, diagnosticated the condition fibroid polypus, and referred the case to me for treatment.

She was quite pale, lips bloodless; complained of pelvic pain, and of a constant bloody discharge, which amounted to hemorrhage upon the slightest exertion. The vagina was dilated by a tumor the size of an orange, about whose pedicle could be felt the neck of the uterus. The finger passed into the os and about the tumor without difficulty. Every examination was followed by severe hemorrhage. The pedicle was cut through by means of the wire écraseur, and the polypus removed by means of a pair of polypus-forceps. Considerable hemorrhage followed its removal. As this was not controlled by applications of hot water, a tampon saturated with a solution of subsulphate of iron was introduced. This was removed on the second day. On the fourth, her temperature ran up to 103°, she had a chill, and pains in various parts of her body. These symptoms vanished under the use of quinine, digitalis, and opium. Five weeks after the operation she appeared much improved, has had no bleeding since, her appetite and strength are greatly increased, the uterus was normal in size, the cervix still dilatable and will admit the finger with pressure. The cervical membrane was in good condition.

The tumor was the size of an orange. The mucous membrane of the lower surface was ulcerated so that vessels were ruptured, allowing hemorrhage on any exertion.

The case is of interest from the long continuance of the hemorrhage, and illustrates the importance of early and careful examination of the cavity of the uterus in cases of protracted hemorrhage.

Dr. GOODELL now seldom uses the wire for the removal of uterine polypi. He prefers traction with twisting, or enucleation by the finger. There is less bleeding, and he is afraid of "cupping" of the fundus uteri and its injury by being included in the wire loop. He had made traction with the obstetric forceps and enucleated tumors so large as to rupture the perineum, even after lateral incisions had been made in the labia. He has partially inverted the womb, enucleated the tumor, and then restored the organ to its proper form. The tumor sometimes occludes the os, and fetid pus from necrosis of the growth is imprisoned above it, giving rise to a suspicion of cancer.

Dr. BAER thinks Monsel's solution may have caused the high temperature; vinegar would have been a better hæmostatic, and it is also an antiseptic. From the appearance of the specimen, a portion of the adventitious growth seems to have been left behind, and it would be interesting to know the history of the stump.

Dr. PARISH has removed many fibroids of various sizes, and sometimes with degenerated tissues and noisome odors. The rapid recovery of Dr. Montgomery's patient was remarkable. It is much to be regretted when any portion of the tumor is left, as necrotic change is rapid and decided in such tissue, and there is danger of blood-poisoning. The pedicle, however, generally shrinks and disappears.

Dr. GOODELL remarked that this tumor appeared to be sessile and had been wholly removed. The pedicle proper is usually simply mucous membrane without adventitious tissue, and it makes very little difference if some of it is left behind, as it shrivels away and is absorbed.

Dr. ALLEN sometimes regretted that he was compelled to leave a portion of pedicle or tumor in the uterus; but he has never seen any bad consequences follow it. He prefers vinegar to iron as a hæmostatic, and considers it as good an antiseptic as carbolic acid.

Dr. MONTGOMERY remarked that the wire evidently brought away all the tumor. There

was no evidence of any remnant on examination to-day. In one case a portion of tumor or pedicle was unavoidably left, and he removed it some time afterwards by means of a tenaculum. He wounded his finger in doing so and suffered from septicæmia. The woman had an attack of cellulitis.

W. H. H. GITHENS,
Secretary.

REVIEWS AND BOOK NOTICES.

ANNUAL REPORT OF THE SUPERVISING SURGEON-GENERAL OF THE MARINE HOSPITAL SERVICE OF THE UNITED STATES FOR THE FISCAL YEAR 1884.

The report of the operations of the Marine Hospital Service for the year 1884 is contained in a volume of over three hundred pages. Forty-four thousand seven hundred and sixty-one patients received treatment during the past year,—thirteen thousand and seventy-eight were hospital patients, and thirty-one thousand six hundred and seventy-three were dispensary patients.

The expenditures for the past year were nearly five hundred thousand dollars, showing something of the importance of the service.

The hospital tax which has heretofore been the support of the Service has been abolished, and in its place support has been attempted by the receipts from the duties on tonnage. It was expected that these duties would more than cover the expenses of the Service, but a deficiency instead will amount to at least one hundred and seventy-five thousand dollars.

A very instructive decision by Judge Clarke, concerning the obligations of owners of vessels to seamen, is given. It is held that "a sailor injured in port, while in the performance of his duties as an employé of a vessel, is not obliged to go to a hospital, and that the necessary expenses for his care and treatment while injured in his lawful employment is a charge on the vessel, and the Marine Hospital Service is 'simply auxiliary' to the ancient maritime law which provides that seamen injured in the ship's service have the right to be cared for at the ship's expense."

New regulations for the government of the Service have been completed within the past year.

The physical examination of seamen can now be systematically carried on under the regulations of the Commissioner of Navigation. The Service also furnishes pilots with careful examinations for color-blindness and issues the necessary certificates. Applicants for admission into revenue marine, light-house, and life-saving stations can also receive examination by the medical officers of the Marine Hospital Service. The Surgeon-General recommends that, besides the examination for color-blindness in pilots, further examination and tests be made for acuteness of vision and hearing. This recommendation, in view of the many recent disasters caused by failure in these points, is an important one, and it is to be hoped will be approved—and carried out.

For the protection so necessary against the spread of smallpox, excellent provisions, so far as possible, have been made, and all medical officers receive abundant supplies of fresh, genuine vaccine virus.

All officers and crews of vessels can receive vaccination free of charge. This excellent provision is opposed by some steamboat captains, because it involves the loss of time in their employés incident to the sore arm which follows successful vaccination.

The perils of winter navigation are referred to, and the severe weather of last winter, which passed over so much of our country during the month of January, caused two hundred and thirteen cases of frost-bite to be treated by the Service. These cases were so severe as to require three capital operations, one each of leg, ankle, and foot, and fifteen minor amputations. The hospitals required extra supplies to accommodate the unusual number admitted on this account. This one experience must be a sufficient proof of the importance of the Service and the justice of affording every possible facility for the humane care of our fast dispersing seamen. New hospitals have been built at Cairo, Illinois, Cincinnati, Ohio, New Orleans, Louisiana, and Baltimore, Maryland.

The management of the various hospitals scattered throughout the country from Maine to California, considering the limited funds at the disposal of the Surgeon-General, requires the greatest skill and foresight, and this Dr. Hamilton has accomplished in the face of all obstacles and in a manner which deserves the highest praise. The executive ability which he has displayed in this direction at least entitles him to the confidence of the administration, and few men who had not received a military training could handle so great an undertaking successfully.

The United States Quarantine Service still remains under the officers of the Marine Hospital Service. It is in the proper management of this department that the Surgeon-General must find the greatest obstacles. The funds for carrying on this work are very limited, and the recommendations of the Surgeon-General do not meet with the prompt attention that they should. Untiring energy and skill have been used to make this extra duty successful, and much good has been accomplished. It is hoped that another year this department will be more efficient, and that all the recommendations of Dr. Hamilton will be adopted. The system of reports from foreign countries is carefully carried out, and is of great value. In the present outbreak in

Canada, the value of a trained Quarantine Service is readily recognized. The work of the Service is a direct benefit to our feeble commerce, and if any hope of renewed life exists the importance of the Marine Hospital Service must increase. In no case can it diminish, and to fortify those who are now skilled in its management is an act of simple justice.

The Report contains valuable statistical matter occupying over sixty pages, followed by an interesting report of surgical operations and selected cases from hospital practice. Drs. Austin, Bryan, Armstrong, and Stewart contribute some very important papers. There is also a section of reports of fatal cases with autopsies, and a very instructive chapter on "Yellow-Fever Epidemics." A report on the sanitary condition of Vera Cruz, Mexico, by Dr. Mainegra, and another on Pensacola and vicinity by Dr. Bouvier, are also very instructive. Some reports from United States consuls on the European cholera epidemic of 1884 close the volume.

The Report, on the whole, is excellent, and a credit to the Supervising Surgeon-General, who has worked so faithfully to elevate the Service and make its operations valuable and efficient. W. T. P.

A System of Practical Medicine by American Authors. Edited by William Pepper, M.D., etc.; assisted by Louis Starr, M.D. Volume III.—Diseases of the Respiratory, Circulatory, and Hæmatopoietic Systems. Philadelphia, Lea Brothers & Co., 1885. 8vo, sheep. Pp. 1032.

This volume is more comprehensive, and, as a rule, the individual articles which it contains are more compendious, than some of those which have previously been issued.

It contains articles from twenty-seven contributors upon forty-five subjects: twenty-nine upon diseases of the respiratory system; twelve upon diseases of the circulatory system; and four upon diseases of the blood and hæmatopoietic system. Two posthumous articles appear from the pen of the late Prof. Elsberg, upon diseases of the larynx and trachea respectively.

Among the papers especially deserving mention are those by Austin Flint, M.D., on "Pulmonary Phthisis (Fibroid Phthisis, or Chronic Interstitial Pneumonia);" by Harrison Allen, M.D., on "Diseases of the Nasal Passages;" by Carl Seiler, M.D., on "Laryngoscopy and Rhinoscopy;" by Abraham Jacobi, M.D., articles on "Acute Catarrhal Laryngitis" and "Pseudo-Membranous Laryngitis;" by N. S. Davis, M.D., on "Diseases of the Bronchi;" by Alfred Loomis, M.D., on "Croupous Pneumonia;" by Frank Donaldson, M.D., on "Diseases of the Pleura;" by E. T. Bruen, M.D., on "Syphilitic Diseases of the Lung, Pneumokoniosis, Cancer and Hydatids of the Lung;" and by the editor, on "Croupous Pneumonia." Among those upon Disorders of the Circulatory Apparatus are to be found contributions by J. M. Da Costa, M.D., on "Diseases of the Pericardium;" by Alfred L. Loomis, M.D., on "Endocarditis and Cardiac Valvular Disease;" by William Osler, M.D., on "Diseases of the Substance of the Heart;" by Morris Longstreth, M.D., on "Cyanosis and Congenital Anomalies;" by Beverly Robinson, M.D., on "Cardiac Thrombosis;" by Austin Flint, M.D., on "Neuroses of the Heart;" by John B. Roberts, M.D., on "The Operative Treatment of Pericardial Effusions;" by Andrew H. Smith, M.D., on "Diseases of the Veins, and on the Caisson Disease;" by G. M. Garland, M.D., on "Diseases of the Aorta;" by Elbridge G. Cutler, M.D., on "Diseases of the Coronary and other Arteries;" and by E. T. Bruen, M.D., upon "Diseases of the Mediastinum."

The third series of articles are upon "Diseases of the Blood and Blood-Glandular System," by William Osler, M.D.; on "Diseases of the Spleen," by I. E. Atkinson, M.D.; on "Diseases of the Thyroid Gland," by D. Hayes Agnew, M.D.; and on "Simple Lymphangitis," by Samuel C. Busey, M.D. A Table of Contents and a good Index are contained in the volume.

In the article by Dr. W. H. Geddings on "Hay-Asthma," which otherwise is an excellent *résumé* of the subject, it seems strange to find no mention whatever of the work of Mackenzie of Baltimore or of Sajous of Philadelphia, who have probably done more than any others towards placing the operative treatment of the affection upon a scientific basis. In several of the articles the terminology of the United States Pharmacopœia is not always adhered to; but, in mentioning such small oversights, we merely emphasize the expression of the general excellence of the work, a complete review of which would require more space than we have at our command. The book is uniform with the others, which in typography and press-work are all that can be desired. F. W.

A Treatise on Practical Chemistry and Qualitative Inorganic Analysis. By Frank Clowes, D.Sc. Third American, from the fourth English edition. 14+376 pp. 12mo. Philadelphia, Lea Brothers & Co.

For the third American edition of a laboratory guide which has met with much favor in this country, the author has prepared a special preface. The book has been enlarged, and is arranged in seven sections. I., the preparation and use of apparatus; II., experiments illustrating the preparation and properties of certain gases and liquids; III., analytical operations; IV., analytical reactions; V., analysis of simple substances containing one metal and one acid radical; VI., full analytical course and tables; VII., laboratory fittings, apparatus, chemicals, and reagents.

The plan is good, and the new edition is unquestionably an improvement, but there are some grave errors in logical sequence,—the first requisite of an elementary book. What idea can the student form of chemical equations until some information of the notation involved in those equations is imparted? Yet, on page 16, we learn that oxygen is set free "as shown by the following equation," and equations are freely used in Section II., although chemical notation is not mentioned before page 73, in Section IV. On page 94 we are told that "the dashes following the symbol (Fe) denote the number of chlorine atoms, or their equivalent, which are combined with one atom of Fe in its compounds," but we look vainly for the import of "the equivalent" of chlorine atoms.

The analytical methods given are usually good, and a pupil having a previous knowledge of general chemistry or a good teacher may make fair progress by the aid of the book, but it is hardly adapted as a text-book for beginners who must learn only by personal experience.

Section VII., on Laboratory Fittings, contains much useful information and valuable hints for teachers and laboratory directors.

W. H. G.

NEW BOOKS.

LESSONS IN HYGIENE. An Elementary Text-Book on the Maintenance of Health. With the Rudiments of Anatomy and Physiology, and the Treatment of Emergent Cases. Comprising also Lessons on the Action of Stimulants and Sedatives on the Brain and Nervous System. Adapted for Common Schools. By JOHN C. CUTTER, B.S., M.D. Illustrated. Philadelphia, J. B. Lippincott Company. 1885. Pp. 180.

VON ZIEMSSEN'S HAND-BOOK OF GENERAL THERAPEUTICS. In Seven Volumes. Vol. I. Introduction by PROFESSOR H. VON ZIEMSSEN. On the Dietary of the Sick and Dietetic Methods of Treatment. By PROFESSOR J. BAUER. On the Koumiss Cure. By DR. STANGE. Translated from the German by EDWARD F. WILLOUGHBY, M.D. (Lond.). New York, William Wood & Co., 56 and 58 Lafayette Place. 1885. Pp. 408.

Vol. II. Antipyretic Methods of Treatment. By PROFESSOR TH. JÜRGESSEN. Epidermic, Endermic, and Hypodermic Administration of Medicines. By PROFESSOR A. EULENBURG. With Twelve Illustrations. Translated by MATTHEW HAY, M.D., of Aberdeen. Pp. 511.

Vol. III. Respiratory Therapeutics. By PROFESSOR M. J. OERTEL, M.D., of Munich. Translated by J. BURNEY YEO, M.D. Pp. 769.

A TEXT-BOOK OF MEDICAL PHYSICS. For the Use of Students and Practitioners of Medicine. By JOHN C. DRAPER, M.D., LL.D. With Three Hundred and Seventy-seven Illustrations. Philadelphia, Lea Brothers & Co. 1885. Pp. 733.

THE TEN LAWS OF HEALTH; OR, HOW DISEASES ARE PRODUCED AND PREVENTED; AND FAMILY GUIDE TO PROTECTION AGAINST EPIDEMIC DISEASES AND OTHER DANGEROUS INFECTIONS. By J. R. BLACK, M.D. Philadelphia, J. B. Lippincott Company. 1885. Pp. 413.

POISONS: THEIR EFFECTS AND DETECTION. A Manual for the Use of Analytical Chemists and Experts. With Introductory Essay on the Growth of Modern Toxicology. By ALEXANDER WYNTER BLYTH, M.D., etc. With Tables and Illustrations. Vols. I. and II. New York, William Wood & Co., 56 and 58 Lafayette Place. 1885. Pp. 333—668.

A TREATISE ON ASIATIC CHOLERA. Edited and Prepared by EDMUND CHARLES WENDT, M.D., in association with DRS. JOHN C. PETERS, of New York; ELY MCCLELLAN, U.S.A.; JOHN B. HAMILTON, Surgeon-General United States Marine Hospital Service; and GEORGE M. STERNBERG, U.S.A. Illustrated with Maps and Engravings. New York, William Wood & Co., 56 and 58 Lafayette Place. 1885. Pp. 403.

ON RENAL AND URINARY AFFECTIONS. By W. HOWSHIP DICKINSON, M.D., etc. Miscellaneous Affections of the Kidneys and Urine. New York, William Wood & Co., 56 and 58 Lafayette Place. 1885. Pp. 343.

CANCER: A STUDY OF THREE HUNDRED AND NINETY-SEVEN CASES OF CANCER OF THE FEMALE BREAST. WITH CLINICAL OBSERVATIONS. By WILLARD PARKER, M.D. New York and London, G. P. Putnam's Sons. 1885. Pp. 61.

LECTURES ON DISEASES OF THE NERVOUS SYSTEM, ESPECIALLY IN WOMEN. By S. WEIR MITCHELL, M.D. Second Edition, Revised and Enlarged. With Five Plates. Philadelphia, Lea Brothers & Co. 1885. Pp. 283.

SECOND REPORT OF THE STATE BOARD OF HEALTH OF THE STATE OF TENNESSEE. October, 1880—December, 1884. Published by Authority. Nashville. 1885. Pp. 570.

INEBRIISM: A PATHOLOGICAL AND PSYCHOLOGICAL STUDY. By T. L. WRIGHT, M.D. Columbus, Ohio, William G. Hubbard. 1885. Pp. 222.

LARYNGOSCOPY AND RHINOSCOPY IN THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE THROAT AND NOSE. By PROSSER JAMES, M.D. Fourth Edition, Enlarged. Illustrated with Hand-Colored Plates. New York, William Wood & Co., 56 and 58 Lafayette Place. 1885. Pp 223.

MEDICAL THOUGHTS OF SHAKESPEARE. By B. RUSH FIELD, M.D. Second Edition. Revised and Enlarged. Easton, Pennsylvania, Andrews & Clifton, Publishers. 1885. Pp. 86.

AN INTRODUCTION TO THE STUDY OF THE DISEASES OF THE NERVOUS SYSTEM: BEING LECTURES DELIVERED IN THE UNIVERSITY OF EDINBURGH DURING THE TERCENTENARY YEAR. By THOMAS GRAINGER STEWART, M.D. Philadelphia, J. B. Lippincott Company. 1885. Pp. 237.

A TREATISE ON NERVOUS DISEASES; THEIR SYMPTOMS AND TREATMENT. A Text-Book for Students and Practitioners. By SAMUEL G. WEBBER, M.D., etc. New York, D. Appleton & Co., 1, 3, and 5 Bond Street. 1885. Pp. 415.

TRACHEOTOMY IN LARYNGEAL DIPHTHERIA; AFTER-TREATMENT AND COMPLICATIONS. By ROBERT WILLIAM PARKER, M.D. Second Edition, Revised and Considerably Enlarged. London, H. K. Lewis, 136 Gower Street, W.C. 1885. Pp. 124.

URINARY AND RENAL DERANGEMENTS, AND CALCULOUS DISORDERS. HINTS ON DIAGNOSIS AND TREATMENT. By LIONEL S. BEALE, M.D. Philadelphia, P. Blakiston, Son & Co., 1012 Walnut Street. 1885. Pp. 356.

BERLIN AS A MEDICAL CENTRE: A GUIDE FOR AMERICAN PRACTITIONERS AND STUDENTS. By HORATIO R. BIGELOW, M.D., etc. (Reprinted from the *New England Medical Monthly*.) Sandy Hook, Connecticut. New England Publishing Company. 1885. Pp. 117.

A TREATISE ON PRACTICAL CHEMISTRY AND QUALITATIVE INORGANIC ANALYSIS. Adapted for Use in the Laboratories of Colleges and Schools. By FRANK CLOWES, D.Sc. Lond. With Illustrations. From the Fourth English Edition. Philadelphia, Lea, Brothers & Co. 1885. Pp. 376.

THE TREATMENT OF OPIUM-ADDICTION. By J. B. MATTISON, M.D. New York and London, G. P. Putnam's Sons. 1885. Pp. 49.

ELEMENTS OF MODERN MEDICINE; INCLUDING PRINCIPLES OF PATHOLOGY AND THERAPEUTICS. WITH MANY USEFUL MEMORANDA AND VALUABLE TABLES FOR REFERENCE. Designed for the Use of Students and Practitioners of Medicine. By R. FRENCH STONE, M.D. New York, D. Appleton & Co., 1, 3, and 5 Bond Street. 1885. Pp. 368.

A GUIDE TO SANITARY HOUSE-INSPECTION: OR, HINTS AND HELPS REGARDING THE CHOICE OF A HEALTHFUL HOME IN CITY OR COUNTRY. By WILLIAM PAUL GERHARD, C.E. New York, John Wiley & Sons. 1885. Pp. 138.

THE USE OF THE MICROSCOPE IN CLINICAL AND PATHOLOGICAL EXAMINATIONS. By Dr. CARL FRIEDLANDER. Second Edition, Enlarged and Improved, with Chromo-Lithograph. Translated, with Permission of the Author, by HENRY C. COE, M.D. New York, D. Appleton & Co., 1, 3, and 5 Bond Street. 1885. Pp. 195.

MASSACHUSETTS EMERGENCY AND HYGIENIC ASSOCIATION. Six Lectures upon School Hygiene. Delivered, under the Auspices of the Massachusetts Emergency and Hygienic Association, to Teachers in the Public Schools. Boston. Published by Guire & Co. 1885. Pp. 193.

NEW REMEDIES AND CLINICAL NOTES.

IODOFORM COLLODION IN NEURALGIAS.—Dr. William Browning, of Brooklyn, in the October number of *The American Journal of the Medical Sciences*, gives his experience with this remedy for external application, together with notes on the preparation itself, and a brief study of its action. The strength usually employed is one part of iodoform to fifteen of collodion. A half-ounce is usually sufficient for any ordinary single application. Dr. Browning has found it most effective when painted on in very thick layers, which may be conveniently done with the usual camel's-hair brush. As soon as one coating becomes a little firm another is applied, and so on until it appears to have an average thickness of half a millimetre. In the neuralgic cases a cure, when effected, was usually accomplished with one or two applications.

The class of troubles found most amenable to this treatment was narrowly localized neuralgias, especially when corresponding to some particular nerve and not dependent on any demonstrable lesion. In fact, if a neuralgia, or what is thought to be one, proves intractable to this means, we should doubt its being a purely functional affection, and look carefully for some tangible cause. It has thus a certain diagnostic, as well as a therapeutic, value. Several times its complete or partial failure has led to a more searching and successful examination. Even in such cases much temporary relief is often afforded.

Supraorbital neuralgias, even of malarial origin, particularly if the miasmatic infection dates back some time, seem quite amenable to this treatment. Of course it is not recommended as a substitute for quinine here, but only as an adjuvant where the latter fails or acts too slowly.

EFFECTS OF PEPSIN IN LARGE DOSES.—Dr. Rassmann reports to the *Medical Record* (p. 346) the case of a man suffering with dyspepsia, for whom pepsin was ordered, fifteen grains after each meal, to be taken with a dose of hydrochloric acid. The patient, in order to test the effects of the remedy, took twenty powders, or five drachms of pepsin, in one dose, just before retiring. The effects are thus described:

"In about an hour he was seized with an intense burning pain in the epigastrium, accompanied by nausea, and three hours later with violent colicky pains and diarrhœa. These symptoms continued until nearly noon of the following day, when they disappeared, leaving only a moderate amount of nausea, burning in the epigastrium, and a feeling of exhaustion. There was no vomiting. . . . . Nothing had been taken to counteract the effects of the drug. The pepsin had been procured from a reliable apothecary, and there was no reason to suspect that it was not pure and of full strength. The solution of hydrochloric acid was not touched."

[Although not so stated, it was, in all probability, saccharated pepsin which was taken. It would have been interesting to determine how long the preparation of pepsin had been made, and also to have had some of the pepsin examined, to detect possible adulteration or the presence of ptomaines.]

HYDRONAPHTHOL: A NEW ANTISEPTIC.—Dr. George R. Fowler, in a communication to the *New York Medical Journal*, speaks highly of hydronaphthol as an antiseptic agent, which in efficiency is only surpassed by mercury bichloride. It is soluble in cold water to the extent of one part in two thousand, in which strength it will not destroy germs, but it prevents the development of spores. From some comparative experiments, it was determined that "as an antiseptic it is about one-fifth as powerful as the mercury bichloride; from one and a half to double the strength of iodine; four times as strong as sulphuric acid; at least twelve times as efficient as carbolic acid; thirty times as potent as salicylic acid, when sodium biborate is added to the latter (for the purpose of increasing its solubility) in the proportion of equal parts of each; thirty times as powerful as both boric acid and ferric sulphate; sixty times as strong as sodium biborate; and six hundred times as strong as alcohol."

Hydronaphthol solution may be used for irrigation in the spray, and for washing instruments and the hands of the surgeon, and with wood-wool, sawdust, and other dressings. The crystals are soft and have especial advantages for making antiseptic gauze, and a good substitute for iodoform, as a dressing-powder, is obtained by adding hydronaphthol to magnesium carbonate in the proportion of two to one hundred.

STRYCHNINE IN SPINAL AFFECTIONS.—Dr. Landon Carter Gray, in the October number of *The American Journal of the Medical Sciences*, reports five cases which, as far as they go, demonstrate that strychnine was not well borne by two cases of severe acute myelitis, or by two subacute cases of mild poliomyelitis anterior; that one-twenty-fifth of a grain, continued for four days in a case of trans-

verse myelitis with early extension to the lateral columns, given three months after onset, suddenly induced alarming toxic symptoms; that one chronic case of general myelitis of traumatic origin was greatly benefited, as was also a case of general myelitis in which the onset had been gradual; that in five cases of progressive muscular atrophy it acted as a remarkable stimulant; that, as Dr. Weir Mitchell has indicated, it was decidedly beneficial in cases of neurasthenia, which, after being treated by some eight to ten weeks of rest and forced feeding, were taken out of bed, although it failed to agree with three cases of neurasthenia treated in the ordinary way.

Effects of a Large Dose of Tincture of Digitalis.—A woman swallowed three fluidounces of tincture of digitalis. Within a few minutes intense vomiting set in and a large portion of the drug was rejected, this being aided by emetics administered at the Hôpital Saint-Louis, where the patient was at once carried. Subsequently two sets of symptoms appeared: those attributable to gastric irritation (vomiting, pain), and those manifested in the circulation (irregularity and slowness of the pulse, violent delirium, cutaneous hyperæsthesia, muscular hemiparesis, vertigo, amblyopia, and xanthopsia). The treatment was stimulating: hypodermic injections of ether, ammonium carbonate, strychnine, and, later, frictions, electricity, atropine, and a carefully regulated diet. Recovery was complete on the eighth day.—*Le Concour Médical* and *Med. and Surg. Rep.*

Chloroform for Tape-Worm. — After failing with male fern, Dr. Perry, of San Francisco, in the case of a man who had suffered with tape-worm for eight years, succeeded in dislodging it in the following manner: The patient was made to fast from noon of the preceding day, and only permitted to drink lemonade. At seven o'clock in the morning he took one drachm of chloroform in one ounce of mucilage, and one hour later an ounce of castor oil. The patient was in considerable stupor shortly after taking the medicine, which stupor lasted three or four hours. He was a large man, weighing one hundred and eighty pounds. Dr. Perry thinks that the dose of one drachm of chloroform should not be exceeded.

Chloral in Tetanus Infantum.—In the *Dublin Journal of Medical Science* for September, Mr. Henry May reports a case of convulsions occurring on the seventh day after birth of a female child who at birth had been a strong, healthy infant. Cause of convulsions unknown. The treatment was as follows: the food consisted of a teaspoonful of brandy, one-third of a teacupful of fresh cow's milk mixed with two-thirds of warm water, slightly sweetened. Of this the mother managed to give about three teacupfuls in the twenty-four hours, and a teaspoonful of the following was ordered every third hour:

℞ Chloral. hydratis,
Potass. bromid., āā gr. xvj;
Ext. ergot. liq. (Sorg's), ℥xlviij;
Glycerini, ʒiij;
Aquæ destillatæ, ad fʒiv. M.
Fiat mistura.

The treatment was continued, though less actively as the symptoms improved, for fourteen days, when the child took the breast again and afterwards gradually recovered.

Aquapuncture as a Substitute for Injections of Cocaine.—Dr. W. T. Halstead reminds us of the fact that has recently been lost sight of, that the skin can be anæsthetized by subcutaneous injections of water, and he has used it for local anæsthesia as a substitute for cocaine in minor surgical operations. The anæsthetic effect is limited to the boundary of the original bloodless wheal, but does not always vanish as soon as hyperæmia supervenes.—*N. Y. Med. Journal.*

Boroglyceride in Psoriasis.—Dr. Chas. Roberts, in an irritable and obstinate case of psoriasis, used boroglyceride locally with very gratifying results, and has since used it in other cases with the same effect.—*Brit. Med. Journal.*

Wiring Bones.—An ingenious modification of the procedure and some new instruments for wiring bones together are described in a communication to the *Medical Record* for September 26, by William F. Fluhrer, M.D.

MISCELLANY.

Messrs. Parke, Davis & Co. announce that they will furnish a collection of all crude drugs of vegetable origin recognized in the United States Pharmacopœia, and, in addition, some unofficinal remedies in common use. The specimens number two hundred and eighty-eight in all, contained in a black walnut case, in wooden boxes, each bearing a label with its number, by which it can be identified in the alphabetically-arranged index. If the manufacturers receive orders from a sufficient number (fifty subscribers), they will furnish these cabinets at ten dollars apiece.

As a help to the study of materia medica and pharmacognosy, this collection would be of great value to students.

Drs. W. H. Warder and E. E. Montgomery have opened a private hospital for diseases of women at 1409 Thompson Street, Philadelphia.

NOTES AND QUERIES.

NOTICE TO OCULISTS AND PUBLISHERS ON OCULISTIC MATTERS.

Having taken charge of reporting for the *Revue Générale d'Ophthalmologie*, edited by Dr. E. Meyer, of Paris, and Dr. Dor, of Lyon, on the progress of ophthalmology in our country, I beg leave to request all authors and publishers of ophthalmic works and papers to send me copies or reprints of their respective publications, in order to enable me to give the most complete review of the current ophthalmic literature of this country in a periodical of the largest circulation among our profession. (Medical papers please copy.)

DR. M. LANDESBERG,
40 West Thirty-fourth Street, New York.

OBITUARY.

JOHN LIGHT ATLEE, M.D., one of the few ex-Presidents of the American Medical Association, and one of the most distinguished physicians of this country, died at his home in Lancaster, in this State, on the 1st inst., from an attack of pleurisy, after having been rendered almost an invalid from an attack of hemiplegia which occurred about two years ago.

Dr. Atlee was born in Lancaster, November 2, 1799, and was the son of Colonel William Pitt Atlee, of Revolutionary fame. He was graduated from the University of Pennsylvania in 1820, after five years' course of study. In his address as President of the American Medical Association, delivered in Cleveland two years ago, he gave many interesting reminiscences of the profession and medical teaching in Philadelphia in the first quarter of this century. In a long and useful life devoted to his profession, Dr. Atlee, although practising in his native city, acquired a reputation that was more than national. He was one of the originators of the Lancaster City and County Medical Society in 1843, and twice was its presiding officer. He assisted in forming the Pennsylvania State Medical Society in 1848, and was active in the organization, in 1847, of the American Medical Association, in each of which he was honored by being elected to the highest office.

Always warmly interested in matters of education, he was for forty years a school director, and a trustee of Franklin and Marshall College, in which institution he also filled the Chair of Professor of Anatomy and Physiology for many years. He was President of the Board of Trustees of the Home for Friendless Children, and of the State Lunatic Asylum at Harrisburg. He was a member of a number of scientific societies, including the American Gynæcological Association and the College of Physicians of Philadelphia. In co-operation with his eminent brother, Dr. Washington L. Atlee, he labored successfully in establishing the operation of ovariotomy upon a firm foundation, and in 1843 performed the first operation of double ovariotomy upon a patient who survives him. As a surgeon he was skilful and successful, and had won a well-earned reputation in the surgery of the abdomen before modern methods, with their rigid rules, had been devised. Dr. Atlee was not a frequent contributor to medical journalism, but this was attributable to his great modesty, and not to want of ability as a writer or lack of material and opportunity for observation.

Dr. Atlee was married, in 1822, to the eldest daughter of Hon. Walter Franklin, president judge of the courts of Lancaster and York Counties. His son, Walter F. Atlee, is a resident of Philadelphia.

Dr. John L. Atlee was a man with high ideals of duty, integrity, and professional honor. He served his generation well, and "bore without reproach the grand old name of gentleman."

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 27, 1885, *TO OCTOBER* 10, 1885.

COLONEL T. A. MCPARLIN, SURGEON.—Directed to transfer his duties, and the public funds for which he is accountable as assistant medical purveyor, to Captain Henry Johnson, Medical Storekeeper, who will, in addition to his present duties, temporarily perform the duties of assistant medical purveyor, New York City. S. O. 223, A. G. O., September 29, 1885.

MAJOR D. G. CALDWELL, SURGEON.—Ordered from Fort Laramie, Wyoming, to Fort D. A. Russell, Wyoming. S. O. 97, Department of the Platte, September 28, 1885.

CAPTAIN J. H. BARTHOLF, ASSISTANT-SURGEON.—Ordered from Fort Ringgold, Texas, to Fort McIntosh, Texas, for duty as post-surgeon. S. O. 125, Department of Texas, September 28, 1885.

CAPTAIN DANIEL WEISEL, ASSISTANT-SURGEON.—To be relieved from duty at Camp at Rock Springs, Wyoming, and return to his proper station, Fort Fred Steele, Wyoming. S. O. 99, Department of the Platte, October 1, 1885.

CAPTAIN G. W. ADAIR, ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 232, A. G. O., October 9, 1885.

CAPTAIN VICTOR BIART, ASSISTANT-SURGEON.—Sick-leave of absence further extended six months, on surgeon's certificate of disability. S. O. 227, A. G. O., October 3, 1885.

CAPTAIN LOUIS BRECHEMIN, ASSISTANT-SURGEON.—Ordered from Fort D. A. Russell, Wyoming, to Fort Laramie, Wyoming. S. O. 97, Department of the Platte, September 28, 1885.

FIRST-LIEUTENANT G. E. BUSHNELL, ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 215, Department of the East, October 6, 1885.

FIRST-LIEUTENANT C. N. B. MACAULEY, ASSISTANT-SURGEON.—Relieved from duty at Fort A. Lincoln, Dakota Territory, and ordered for duty at Camp Poplar River, Montana Territory.

FIRST-LIEUTENANT WILLIAM L. KNEEDLER, ASSISTANT-SURGEON.—When relieved from duty at Camp Poplar River, Montana Territory, by Assistant-Surgeon Macauley, to report to commanding officer, Fort Snelling, Minnesota, for duty.

S. O. 105, Department of Dakota, September 21, 1885.

FIRST-LIEUTENANT WILLIAM STEPHENSON, ASSISTANT-SURGEON.—Relieved from duty at Fort Niobrara, Nebraska, and ordered for duty at Camp at Rock Springs, Wyoming. S. O. 99, Department of the Platte, October 1, 1885.

FIRST-LIEUTENANT A. R. CHAPIN, ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 230, A. G. O., October 7, 1885.

FIRST-LIEUTENANT P. G. WALES, ASSISTANT-SURGEON.—Relieved from temporary duty at Boise Barracks, and ordered for duty at Fort Cœur d'Alene, Idaho. S. O. 160, Department of Colorado, September 21, 1885.

FIRST-LIEUTENANT C. B. EWING, ASSISTANT-SURGEON.—Relieved from duty at Fort Stanton, New Mexico, and ordered for duty at Fort Leavenworth, Kansas. S. O. 147, Department of Missouri, September 25, 1885.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM SEPTEMBER 27, 1885, *TO OCTOBER* 10, 1885.

SURGEON WILLIAM H. JONES.—To Navy-Yard, League Island, Pennsylvania, October 15, as the relief of Medical-Inspector M. Bradley.

MEDICAL-INSPECTOR MICHAEL BRADLEY.—Detached from Navy-Yard, League Island, Pennsylvania, October 15, and placed on waiting orders.

ASSISTANT-SURGEON THOMAS OWENS.—To Naval Station, New London, Connecticut, as the relief of Surgeon William A. Corwin.

SURGEON WILLIAM A. CORWIN.—Detached from Naval Station, New London, Connecticut, and ordered to the U.S.S. "Adams" October 31.

SURGEON A. F. MAGRUDER.—Ordered to the U.S.S. "Yantic" without delay, as the relief of Surgeon H. L. Law.

SURGEON H. L. LAW.—Detached from the U.S.S. "Yantic," and wait orders.

SURGEON W. J. SIMON.—Detached from the Naval Academy October 1, and wait orders.

SURGEON M. C. DRENNAN.—Detached from the Naval Academy October 1, and wait orders.

PASSED ASSISTANT-SURGEON ARTHUR G. CABELL.—To the U.S.S. "Adams," October 31.

SURGEON GEORGE A. BRIGHT.—To U.S.S. "Brooklyn."

ASSISTANT-SURGEON HENRY B. FITTS.—To Naval Hospital, New York.

PASSED ASSISTANT-SURGEON JOHN H. HALL.—Detached from Naval Hospital, Mare Island, California, and ordered to the "Hartford."

PASSED ASSISTANT-SURGEON ROBERT SWAN.—Detached from Naval Hospital, New York, and ordered to the "Brooklyn."

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, OCTOBER 31, 1885.

ORIGINAL LECTURES.

CLINICAL LECTURE
ON THE VARIOUS FORMS OF SCLEROSIS OF THE SPINAL CORD.

Delivered at the Hospital of the University of Pennsylvania

BY WILLIAM PEPPER, M.D., LL.D.,

Provost of, and Professor of the Theory and Practice of Medicine and of Clinical Medicine in, the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M.D.

GENTLEMEN,—I propose to devote the hour to the study of sclerosis of the spinal cord, of which there are three principal varieties. The first that I shall consider is sclerosis of the lateral columns, or antero-lateral sclerosis. Where the sclerosis of the lateral columns extends into the gray matter so as to involve the nerve-cells, and is associated with muscular atrophy, it produces the affection known as amyotrophic lateral sclerosis, which, however, is simply a complication of lateral sclerosis. The second variety is where the sclerosis is not limited to one column, but occurs in patches scattered irregularly throughout the cord, and sometimes extending into the brain. This is disseminated, insular, or cerebro-spinal sclerosis. The third variety is sclerosis of the posterior columns, or, as it is often termed, from its characteristic phenomenon, progressive locomotor ataxia.

Sclerosis, as you are aware, is a morbid change in the nerve-substance, attended with a breaking down and atrophy of the nerve-fibres, with overgrowth of the interstitial connective tissue. Sclerosis is on the border-line between chronic inflammation and degeneration. The sclerosed parts are grayish, somewhat translucent, and rather smaller than normal.

The causes of sclerosis of the spinal cord are exposure to wet and cold, prolonged overtaxing of the nervous system, particularly of the spinal cord, and excesses in venery. Syphilis is a common cause of sclerosis, and perhaps more particularly disposes to posterior sclerosis; but I warn you not to think in every case of sclerosis, even where there is a history of syphilis, that syphilis is the essential cause of the sclerosis, since the other causes of sclerosis may operate as readily in a person with constitutional syphilis as in one who has not this taint. Sclerosis may also be produced by the extension of a neuritis. The peripheral nerves may become the seat of inflammation, which, creeping upward, invades the cord and lights up a slow process of chronic inflammation and degeneration, ending in sclerosis.

The symptoms of sclerosis of the spinal cord are best studied under the three heads already given. The symptoms of lateral sclerosis are, in the first place, progressive loss of power, not amounting to complete palsy. In the second place, muscular tremor, particularly when the muscles are thrown into action. With this there is muscular twitching and a disposition to contraction. In the third place, increase in the reflex irritability, which may be tested by the knee-jerk. There is also increase in the electro-muscular irritability. Ordinary sensation is not affected. The patient's gait is peculiar, on account of the rigidity of the muscles, but he can walk as well with his eyes shut as with them open. There are no pains connected with this affection, neither darting pains nor the girdle sensation.

The patient now before us illustrates this form of sclerosis. The following history has been obtained:

H. S., aged 28 years, single, is an engineer by occupation, and had been working on a railroad in Wyoming Territory until three or four months ago, when he came to this city. When a child he had diphtheria, which was followed by dropsy and paralysis. Later he was thrown on a hot stove and severely burned, the scar being visible on the epigastrium. When twenty-two years of age he had typhoid fever. He denies having had gonorrhœa or syphilis, although intercourse with loose women is acknowledged. Careful investigation fails to reveal any trace of specific infection. He has used alcohol in considerable quantities, but has never been intoxicated. He uses tobacco in great excess, smoking as many as fifteen cigars on some days, and chewing a large plug of tobacco every twenty-four hours.

His occupation has been an exposing one, subjecting him to extreme alternations of heat and cold. He, however, continued in good health until three years ago. In December, 1882, he first noticed a gradual loss of power in the left ankle. He states that five months prior to this he had injured the left ankle and knee by falling from his locomotive. This kept him in bed for seven days, then ap-

parently became entirely well. This feeling of weakness on the left side compelled him to throw most of his weight on the right leg. The trouble gradually grew worse, and in November, 1883, he noticed that occasionally the affected leg would suddenly fly backward when he attempted to move it, and that the muscles of the left side would tremble violently in a quick clonic spasm. Unless he moved very carefully, this occurred at every step. He next observed that he was losing flesh. His height is six feet one and one-half inches, and his best weight has been one hundred and seventy-nine pounds. Three months ago, when this note was made, he weighed one hundred and sixty-five pounds.

In July, 1884, the affected ankle was strained, and this was followed by swelling of the foot and leg. About this time, or a little earlier, he noticed that the fingers of the left hand were disposed to contract, so that the hand would remain closed until the fingers were forcibly extended. The contraction was increased by fatigue. This gradually grew worse, until it involved the hand, forearm, arm, and shoulder. All the muscles of the arm would quiver when he became tired from exhaustion. In addition, he had a peculiar numbness or tingling over the left side. This is sometimes described as the feeling of pins and needles, and is frequently complained of by patients with nervous affections, particularly when the spinal cord is involved. Some days the patient feels better than on others, and is able at times to walk two or three squares.

During all this time the man has had no severe pain, although he has had occasional vague pains in various parts of the body; but there has been no fixed pain, and no darting, severe, sharp pain, nor has he had any sense of constriction about any part of the chest. His memory is good, and he sleeps well. The appetite is sometimes rather poor, although at times voracious; then he overloads the stomach, and suffers with vomiting. The bowels are constipated. He has occasional palpitation of the heart. The heart beats rather actively, but somewhat irregularly, losing a beat in every ten or fifteen pulsations. The second sound is accentuated, but there is no distinct murmur. There is a trace of albumen in the urine, very slight, however, and diminishing. There are no tube-casts, but a few pus-cells with epithelium from the bladder, so that I regard the albumen as due to the admixture of a little pus with the urine, and not as an indication of renal disease.

There is a little wasting of the muscles of the left side. The following measurements have been taken:

	Right. Inches.	Left. Inches.
Calf	14½	14
Forearm . . .	11¼	11
Biceps . . .	11¼	11¼
Thigh	19	18

When the left biceps is contracted it is not nearly as prominent as the right muscle. There is then a slight diminution in the size of the right side; but when we remember that the man has been throwing his weight on the right leg, and has been using the right arm more frequently than the left, this wasting is no more than would be expected.

Let us note his condition to-day. His right side has not been involved, but he now states that lately there have been shooting pains in the right arm and leg, and that there is some slight twitching of the fingers of the right side. Examining the left arm, we find that there is almost complete paralysis of the shoulder-muscles. The biceps has some power, but the triceps has very little. The extensor of the little finger responds, but the common extensor is almost completely paralyzed. There is more power in the flexors, but this is much impaired. Looking at the muscles of the thigh, we see a marked quivering or fibrillary contraction.

Another marked symptom in this case has been the tendency of the muscles to jerk, so that unless great care were exercised there would be a sudden drawing back of the muscles of the leg when he attempted to advance the foot. This is connected with an increased irritability of the muscle. This, for convenience, is studied by examining the patellar reflex, or, preferably, the knee-jerk. In the normal limb the foot is thrown out when the tendon of the ligamentum patellæ is struck. This is connected with a reflex process, the sensation being transmitted to a segment of the spinal cord, and thence an impulse is carried to the muscles, causing movement. The preservation of the knee-jerk is an evidence of the integrity of this reflex loop from the knee to the spinal cord, and out again to the muscles. It therefore serves as a diagnostic sign of the condition of the spinal cord up to a certain level. There are other reflexes by which the condition of the cord at different levels may be tested. In this man there is a distinct increase in the knee-jerk on the right side, and on the left side it is even more increased.

We have, then, in this man progressive loss of power, unilateral, without affection of the head; fibrillar contractions and tremor of the muscles when they are thrown into action; increased irritability of the muscles, as shown by exaggerated

reflexes; a tendency to contraction; very slight atrophy of the muscles, and a feeling of numbness in the affected part. This affection has been progressive, beginning in the ankle and extending thence to other portions of the left side, and there is now reason to fear that the right side is becoming affected.

I regard this as a case of progressive sclerosis of the antero-lateral columns of the cord, affecting the left side and now extending to the right.

When the sclerosis extends into the gray matter, atrophy is added to the symptoms already mentioned. This, as I have said, constitutes amyotrophic lateral sclerosis. It not infrequently happens that the affection extends upward, involving the pons, and there are then associated symptoms of paralysis of the labio-glosso-laryngeal type, with difficulty of swallowing and failure of voice, and ultimately the sclerosis may involve the brain.

The course of this disease is slow, the cases lasting for years: its tendency is, however, to steady progression. It may involve to some extent the other side. As you know, there is a partial decussation of fibres throughout the spinal cord. Although the chief decussation occurs at the pons, there is at different levels of the spinal cord a partial decussation; consequently, when there is extensive lesion of one side, some of these decussating fibres may be affected, and symptoms referred to the other side appear. This man, as you have heard, shows some symptoms of involvement of the right side. The special senses are unaffected.

I shall reserve my remarks on prognosis and treatment until I have finished the discussion of the other two cases.

I shall next speak of insular or disseminated sclerosis. In this variety the patches of sclerosis are scattered throughout the nervous system. Instead of one column being involved uniformly, the spots of hardening are disseminated throughout the cord. These patches of sclerosis may involve the spinal cord alone, hence spinal sclerosis; or they may involve the brain alone, hence cerebral sclerosis; or, as is more usual, they may involve both the cord and the brain, hence cerebro-spinal sclerosis.

The causes and the morbid anatomy are the same as in sclerosis of the lateral columns. The disease begins gradually, one of the first things noticed being usually a tendency to tremor of the muscle and irregular action, but not true ataxia. Sensation is, as a rule, not affected, pain is absent, and the girdle sensation is wanting. The reflexes are exaggerated, and so is electro-muscular contractility. After the disease has lasted for some time, there is a tendency to involvement of the cerebral centres. The mind becomes affected, the memory fails. Sometimes delusions are present. From time to time acute attacks appear which resemble attacks of cerebral congestion, and sometimes simulate apoplectic attacks. There is usually with these high fever. They last a few days and then subside, leaving the patient worse than before, showing that there has been a development of fresh centres of disease. In these cases there is unsteadiness of gait, but the patient is able to walk about as well with his eyes shut as with them open.

Our second patient is 33 years of age; married at the age of nineteen; is the father of five children, four of whom are living and healthy. He denies having had venereal disease. Seven years ago he had a severe fall, striking on a fence. For six years he has had a hot, full feeling in the head. His gait has been growing more unsteady for years. There have been no fulgurant, excentric pains, and no girdle sensation. At first there was numbness in the hands and feet. There is still some numbness in the hands when they are immersed in water. He eats well and sleeps well. The urine is normal. The trouble in the head came first, then the unsteadiness of gait was noticed. Both the arms and legs are affected, but the latter to a more marked extent. At times he has had vertigo, and his sight has been failing for about four years. There was first double vision and then indistinctness. He states that at intervals he seems to take cold, and afterwards the symptoms are worse.

Both the arms and the legs become tremulous on any attempt at sustained motion. This is most marked in the right leg. There is no atrophy. He has not lost weight. The muscles respond normally to the galvanic current, but a little less than normally to the faradic current. There is slight impairment of the cutaneous sensibility.

The pupils are equal, and respond normally to light. The eyes have been examined by Dr. Norris, who reports that there is partial atrophy of the optic nerve on both sides and that there is contraction of the field of vision. There is no hemiopia and no scotoma. The hearing is normal, the intellect seems to be unimpaired, and memory is good.

We observe from a study of this case that in disseminated sclerosis the symptoms are less regular than in pure lateral sclerosis. Sensibility, as in this man, is sometimes affected, showing that little islets of sclerosis exist in the posterior columns. There are also cerebral symptoms, as shown by the condition of vision and by the emotional and irritable mental condition of the patient. From time to time he has the feverish attacks to which I have referred. These he has attributed to catching cold. In some cases the exacerbations are very severe, and are attended with high fever and even with unconsciousness. Each of these attacks leaves the disease more advanced.

In these two cases the sclerosis chiefly affects the antero-lateral or motor columns of the cord. In the second case, however, there is also some involvement of the posterior columns, as shown by the interference with sensation.

Our next patient will illustrate the third form of sclerosis,—that is, sclerosis of the posterior columns, or progressive locomotor ataxia. The causes of this affection are the same as in the other forms of sclerosis, but in these cases I should attach special importance to the influence of exhaustion from venereal excesses.

In this affection there is what is often termed a pre-ataxic stage, in which the symptoms are chiefly those of irritation. There may be attacks of violent headache resembling sick headache. In other instances there are attacks of acute gastric disturbance termed gastric crises. In such cases the patient is seized with violent and inexplicable disturbance of the stomach, with repeated vomiting. This stage is also marked by disturbed sleep and impaired energy.

Then comes the stage of fulgurant excentric pains. The patient begins to complain of pains darting from one part of the body to another. These are unattended with any signs of inflammation in the affected part. They remain a short time, disappear, and return in another location. There may be with these some rheumatic pains which are more persistent. Next, impairment of sensation is noted. There is numbness and tingling in the legs. Often the soles of the feet are affected, and the patient feels as though walking on a soft carpet or on cotton. Examination shows that there is actual impairment of sensation. The sense of pain also may be diminished. The anæsthesia may be irregularly distributed. There may be here and there spots of diminished sensation, while the sensation of the remaining portions of the limb is normal. The patient may also complain of a girdle sensation around the waist.

Then comes the ataxia, or the incoordination of muscular movements. The strength of the limbs may be perfectly retained, and while sitting the patient may be able to kick out his leg with great force, but when he endeavors to co-ordinate his movements, as in walking, uncontrollable contractions of the muscles of the legs are produced, rendering the gait peculiar and unsteady. If the arms are affected, delicate movements with the hands are impossible. This want of co-ordination is not paralysis, for there is no true paralysis in this disease. The trouble lies in the posterior columns of the cord which carry the impression from the nerves up to the brain, which serves as the stimulus causing a motor impulse to be sent out through the anterior columns, producing co-ordinated movement. These posterior columns are diseased and their fibres irregularly wasted, the sensations are transmitted irregularly and imperfectly, and the motor impulses are correspondingly irregular and imperfect. When the patient attempts to walk, which requires the co-ordinated movement of a large number of muscles, there are irregular contractions of the different muscles and the movements of the extremities become uncontrollable. If the condition is marked, walking becomes impossible. The patient soon has to use a cane, and keep his eyes on his feet when walking. Frequently a man who can walk pretty well while watching the ground will instantly fall if he closes the eyes. Often the first thing that attracts the attention of the patient is the inability to walk in the dark.

The sclerosis follows the course of the posterior columns upward. Beginning with the lower extremity, the muscles are involved at higher and higher levels until the arms are affected. Then disorders of vision, such as diplopia and amaurosis, are often noticed. Ataxia of the globes may be present, so that when the patient attempts to turn his eyes in a particular direction the natural co-ordinated movements are not performed, but the globes

are twisted in different directions. The bladder frequently suffers, and there is partial retention or, on the other hand, incontinence of urine. The expulsive power of the rectum becomes more or less impaired, and retention of fæces is at times a troublesome symptom.

The muscles do not waste to any great extent, but their electro-irritability diminishes. The reflex irritability diminishes decidedly, so that the knee-jerk may disappear. From time to time acute symptoms appear, which, subsiding, leave the condition worse, marking an extension of the disease.

The third patient is F. M., age 54 years, and a carpenter by occupation. His family history is good. He has been a hard-working man. There has been no venereal disease and no sexual excess. For the past five years he has had stabbing pains in the backs of the legs. He has also had the sensation of a cord bound around the waist. He has noticed considerable difficulty in walking in the dark, especially over a rough road. His sight is failing, and sexual desire is lessening. Memory is also failing. The pupils do not respond promptly to light. The sensation seems to be pretty well preserved. Examination shows that the knee-jerk is entirely absent on both sides. Testing the man's ability to stand and walk with his eyes shut, we find that he is able to do this fairly well.

He is evidently in an early stage of this affection, which is excessively slow in its progress. I have seen it run its course in three years, and I have patients under my care who have been ataxic for twenty years or longer.

This loss of reflex irritability is a very important symptom. At the same time, I am not willing to accept the statement of certain authors as to the positive value of loss of the patellar reflex as a proof of established posterior sclerosis. I have seen absent knee-jerk in several conditions of functional spinal disorder, which recovered perfectly and in which there was return of the normal knee-jerk. I have found it in cases of alcoholic paresis and in tobacco paresis. I have seen it in some cases of congestion where organic disease had not been fully established. While I regard the loss of the knee-jerk as a very important sign, and while I regard it as of high diagnostic value when conjoined with stabbing pains, the girdle sensation, failing sight, and difficulty in walking in the dark, yet I hold that the diagnosis of established posterior sclerosis cannot be made from this symptom alone. An active business-man came to me in a state of great alarm, having been told that he had locomotor ataxia. There was nothing to indicate this except a total loss of the patellar reflex. A winter in Florida brought it back.

[The patients were removed.]

We have had, then, illustrations of the three forms of spinal sclerosis. It yet remains for me to speak of the prognosis and treatment. The prognosis in all these forms of disease is exceedingly unfavorable. Their course, though slow, is nearly always progressive. They may extend over a period of from two to twenty or more years. In some cases, however, the disease is arrested. This is true of posterior and lateral sclerosis at least. Of course, in a fully-developed case we rarely can do more than palliate the symptoms.

Where there is marked atrophy and degeneration of the muscles, there is reason to believe that the disease has extended to the gray substance of the cord. In these cases the prognosis is even more unfavorable and the course more rapid than in the other varieties of sclerosis of the spinal cord.

In the treatment of these affections, rest is of importance. The nervous system is weak and irritable, and rest is essential. In fact, rest in bed, when it can be secured, often exerts a powerful influence in checking the progress of the case. I like to confine patients to bed for from sixty to ninety days. This has often mitigated the symptoms to a remarkable degree. When absolute rest is not available, there should be avoidance of exertion, excitement, and fatigue. In these cases too much must not be insisted on. The treatment must be based on a study of the moral as well as the physical condition of the patient, and must be pursued with tact and discretion. Careful avoidance of exposure to damp and cold must be insisted upon. The diet and dress should also receive attention.

If there be a history of syphilis, although you may not feel convinced that the disease has resulted from this taint, yet you will give the patient the benefit of the doubt, and will use antisyphilitic treatment vigorously until you have determined its capacity for good. The iodide of po-

tassium in large doses will usually be found of more service than mercurial preparations. By large doses I mean from ten to thirty grains four times a day. This should not be pursued in a routine manner; but, if there is no evidence of benefit, it should be stopped.

Other alteratives are at times useful. Nitrate of silver has seemed to me to exert a positive influence over the fulgurant pains. I use it in the early stage of posterior sclerosis, where these pains are present. I give it in full doses in quite long courses, alternating it with iodide of potassium in non-syphilitic cases. In syphilitic cases I push the iodide continuously, even if I give the nitrate of silver at the same time. Chloride of gold and silver, which possess some alterative power, has been highly recommended by some authors, but in my judgment it is of much less value than nitrate of silver.

Various alkaline preparations have been used with the idea of inducing absorption at the seat of disease; but I know of no clinical evidences to support this method of treatment. The remedies which I have mentioned I believe to be the most useful.

Special attention must be paid to the secretions, and the condition of the bladder and bowels must be watched.

Counter-irritation I think is useful. I prefer the use of the actual cautery. In the first case, where I think there may be involvement of a nerve-trunk, I have applied it over the sciatic nerve and over the cord. In the second case I have applied it at the base of the brain and over the cervical region. I should select one or other of these points according to the type of disease.

In cases where there is a persistent tendency to contraction I intend to try nerve-stretching, and also where there are marked fulgurant pains in the region of one nerve. I am induced to try this on account of the remarkable influence which stretching of the nerve exercises over symptoms throughout the area of that nerve, and by the fact that irritation extending from a peripheral nerve in so many cases serves to excite the trouble. These facts would justify the experiment,—which is, however, only an experiment.

Manipulation, friction, and electricity, particularly in the form of faradization with a slowly-interrupted, moderate current, are to be recommended.

There are several mechanical devices by which ataxic patients may be enabled to go about. Crutches of peculiar construction, in which the leg is secured to the crutch with bands, often enable the patients to take exercise when otherwise they could not.

ORIGINAL COMMUNICATIONS.

REVIEW OF MEDICAL AND SURGICAL ELECTRICITY.

BY WILLIAM R. D. BLACKWOOD, M.D.,
Neurologist, Presbyterian Hospital.

PRODUCTION OF OZONE BY STATIC MACHINES.

DR. ANDREW H. SMITH, of New York, has devised an ingenious method of utilizing static electricity for the production of ozone as a therapeutic agent, more particularly for inhalation. He constructed a glass cylinder ten inches long by five wide, and introduced a brass rod into each end through a suitable aperture. The rod fitted loosely, so as to permit air to enter, and the inside ends were armed with spherical balls, as found on the ordinary dischargers of the static machine. On one side of the cylinder a short tube was fixed, and the cavity was then loosely packed with fine absorbent cotton. Upon the passage of a strong current from the machine, a volume of ozone is liberated, which is then inhaled directly from the tube or conveyed to any point desired by flexible tubing. Caution is necessary, as ozone is at times very irritating to inflamed or congested mucous membrane both of the throat and eye, as we know from personal experience. Under favorable conditions, this method of generating ozone is preferable to the use of phosphorus for that purpose, and it is free from the danger which attaches to that substance unless confined to the manipulations of the physician.

Mr. Alfred C. Walker, of Chester, England, has recently utilized static electricity in settling dust and fumes developed in the production of lead and zinc salts, which are extremely poisonous to the workmen employed. Connections are made from points whence such fumes arise to a main ventilating, horizontal shaft, preferably of considerable length, through which a current of air is kept flowing. Midway in its length a strong discharge

of static electricity is directed across the duct from a number of blunt rods, and precipitation of all minute solid particles ensues, the deposition being greater near the electrodes, but continuing for some distance beyond, toward the outlet of the shaft. A Wimshurst machine with plates of five feet in diameter was used. The principle is not new; it has long been used as a pleasing experiment with the Leyden jar; but as a hygienic measure in chemical laboratories it is an advance, and the application of something in this direction in the ventilation of pest-wards in hospitals, particularly in quarantine stations, may be desirable.

Vigoroux, as we have before reported, lays stress upon the value of ozone in the atmosphere of cholera-wards produced by static machines; and, whether his ideas are correct or not, it is certainly true, as we have demonstrated by experiment (reported elsewhere*), that microgerms can be sterilized or destroyed by electricity: hence the application of this method to the exhaust ventilating ducts of smallpox or yellow-fever wards is well worth experimenting upon, particularly because it involves little expense.

AN IMPROVED STATIC-ELECTRIC MACHINE.

Messrs. Waite & Bartlett have constructed, at the suggestion of Dr. Ambrose L. Ranney, of New York, a very handsome piece of mechanism, which is an obvious advance on hitherto-existing apparatus. We give the principal features, as stated by Dr. Ranney:

1. The case is so constructed that all of its joints are packed with soft rubber before its screws are tightened. This prevents the entrance of moisture from without, and makes the machine a useful one at all seasons of the year.

Soft rubber now constitutes the best packing for steam-apparatus, and is also used in hermetically sealing fruit-jars in preference to any other known material. All imperfections in the joints of the case are perfectly sealed in this instrument.

The *doors of the case* are so arranged as to be drawn tightly in contact with a frame covered with soft rubber by means of milled screws.

The glass in the case is put into the frames with putty, which is impervious to air.

The poles of the machine perforate the wooden portion of the case instead of the glass windows. They are insulated with hard rubber, and the apertures are protected by soft-rubber packing placed between hard-rubber buttons and the wood. Thus the danger of breakage of the case by accident is decreased without impairing its impermeability to dampness or allowing of leakage of the electricity generated when the machine is in use, while the strength of the case is materially increased by this modification.

2. The axle is so built as to reduce the friction to a minimum and to allow of its being oiled without opening the case.

3. The driving-wheel is very large, and rests upon a cast-iron support. This insures both ease of motion and durability.

4. The glass plates of the machine are nine in number. Six of these revolve and three are stationary. The stationary plates are of peculiar shape. The revolving wheels are made of carefully-selected glass, so as to be as true as possible and bear evenly upon the rubbers as they revolve.

5. The excitants consist of cat-skin rubbers between the inner plates and metal buttons upon the outer plates, which touch as they revolve upon fixed metal brushes.

6. The collectors have tinsel attachments which aid in gathering the electricity generated.

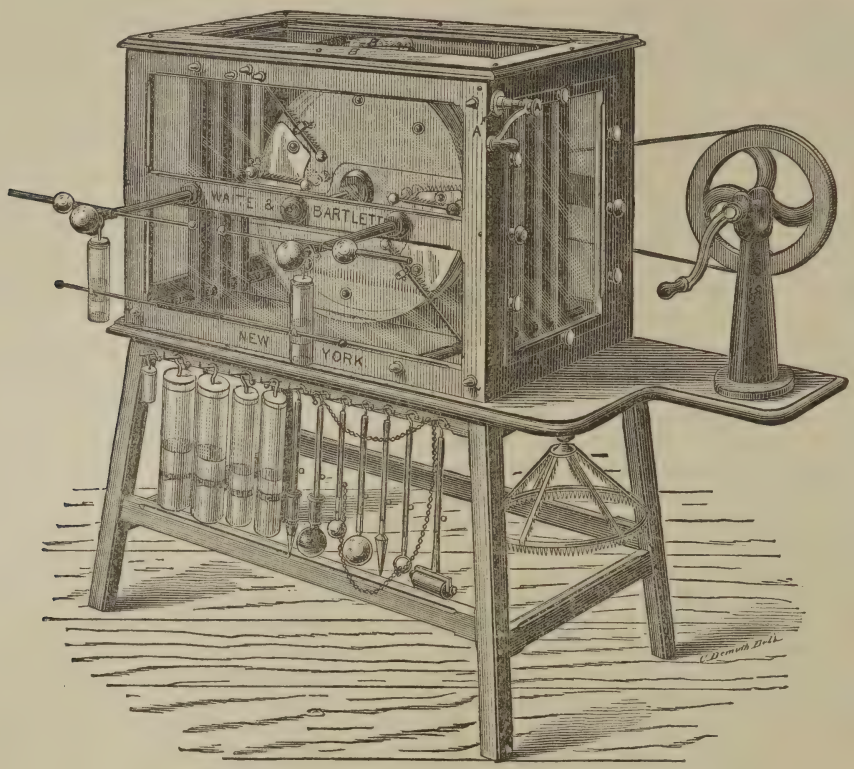
7. The electrodes are made with handles composed of hard rubber instead of glass. They are therefore less liable to be broken, and are as perfectly insulated.

8. Each machine is provided with three pairs of Leyden jars of different sizes. It is arranged also with hooks upon which the electrodes may be hung when not in use.

Sparks eleven inches in length have been obtained during a warm, muggy day in August, which speaks well for efficiency in the new machine.

Mr. D. Rosseau, of 310 Mott Avenue, New York, writes, "I notice in the *New York Medical Record* of the 17th instant the description, by Ambrose L. Ranney, M.D., of a so-called new apparatus for generating static electricity. I am very much surprised at the similarity to the Induction Holtz Machine, manufactured by me for nearly two years. With the exception of the rubber, the principle of the machine was discovered by Holtz, but the new construction, as described by Dr. Ranney,

* Medical Bulletin, December, 1883.



was devised by me, with the help of Charles Van Brunt and H. D. Hall. The first one I sold for medical use was to Dr. M. A. Pallen, in September, 1884; and one to A. C. Hutchinson, President of Morgan's Louisiana and Texas Railroad, also in the fall of 1884; and one to Dr. T. Hamilton Burck, December 18, 1884."

THERMO-ELECTRIC PROSTATOTOMY.

Prof. Bottini, of Pavia, was consulted by a man, æt. 68 years, who was suffering from enlarged prostate. The catheter had to be employed, because of the large amount of muco-pus held in the urine. Irrigations of sulpho-carbolate of zinc and boracic acid toned up the bladder and cleared the urine somewhat. A thermo-electric cautery, consisting of a double-channelled catheter (the inner tube of which holds the conducting wires and the outer permitting a stream of cold water to control the heat in the urethral portion), was used. The platinum plate at the extremity of the loop was applied to the hypertrophied gland for forty-five seconds, and a catheter was then retained in the bladder. Suppositories of belladonna controlled the vesical tenesmus. Sloughs came away in twenty-four days, and micturition was then possible without the catheter. The local use of faradic currents was of benefit, during the course of the case, in toning the parts, and nux vomica was given internally. The procedure is said by Dr. Bottini to be free from much pain, but in sensitive persons chloroform may be used. It is, however, evident that care is demanded, not only against cystitis, but to avoid injury to the vesico-rectal wall, instances of fistula having been produced to our knowledge in operations on the bladder in the hands of competent electro-therapeutists. So long as other reliable methods of treating senile enlargement of the gland exist, it would be well carefully to select such cases as are subjected to electro-cautery.

ELECTRICITY IN GYNÆCOLOGY AND OBSTETRICS.

Hofmeier, of the Royal Berlin University, dwells at length on the value of electro-therapeutics in uterine affections, both

as to the gravid and puerperal states. He is supported by Brumm, of Scanzoni's clinic (who uses faradism), and Baier, of Freund's clinic in Strassburg (who depends upon galvanism). The indifferent results obtained by each of these observers when both electrodes were placed externally are believed by them to be dependent upon the differential value of the two currents; but, if the method used by the reviewer, of *direct intra-uterine* or conjoined applications, had been practised, it would have demonstrated the fact that both currents are equally valuable, although not indifferently applicable to every case. For example, faradism is useful in producing uterine contraction, whatever its condition; but galvanism will act more decidedly in reducing the organ to its normal size if hypertrophied, as in subinvolution. Great dependence is placed upon electricity by each author in dysmenorrhœa and other painful affections of the non-gravid organ.

Vulliet, in the Geneva *Archiv für Gynaecologie*, Band xxii. Heft 3, relates the case of a woman who, having suffered from previous pelvic inflammation, evidenced symptoms of pregnancy, with discharge of decidual membrane. A tumor formed behind the uterus, pushing it forward, and this was incised per vaginam, with no good result. Laparotomy was then done, but the patient died in seventy-two hours from septic peritonitis. Death was undoubtedly due to ill-managed surgical interference. The case was one of extra-uterine pregnancy, and it is referred to as being a typical one for the use of electricity in arresting the development of the ovum,—being almost precisely similar to one under the writer's charge last spring, which terminated favorably, in which faradism produced arrest, and galvanism, later, the absorption of the foreign body. So far we have carefully studied the use of electricity in fifteen cases of extra-uterine pregnancy, four of which were under our own notice, and there is certainly nothing in medicine more fully established than the value and harmlessness of electricity in just such cases as the one above quoted.

INDUCTION OF PREMATURE LABOR BY ELECTRICITY.

Dr. Syromatnikor, in *Vratch*, mentions three methods for inducing labor,—one in which both rheophores are placed externally, one in which an external and an internal pole are used, and the third in which both are used per vaginam. He relates a late case of contracted pelvis, requiring perforation of the head in a previous delivery, and here he employed faradism at the thirty-seventh (?) week through a Sparner's coil (primary). Although pains were produced in an hour, he seems to have required an entire week before completing the work, which implies imperfection, because labor can be readily completed in from twelve to twenty-four hours. The writer mentioned two other cases by Gruenewalt, and one by Typaykoff, all of which were successful.

ELECTRICITY IN INTESTINAL OBSTRUCTION.

Dr. I. J. Hudson relates in the *Medical Times and Gazette* a series of cases occurring in operatives in lead-works and in potteries using lead in glazing their wares. Some of the cases are classed as intussusceptions, but it is probable that all were dependent upon lead-paralysis of the intestinal muscular coat. Dr. Hudson now relies upon galvanism altogether in the treatment of his patients, and the duration of their illness was notably lessened in comparison with the time occupied under other plans of cure. In the potteries the poison is absorbed by the skin, but in the lead-works the process alluded to under the head of "static electricity" would probably have saved much, if not all, of this suffering.

GALVANISM IN ASIATIC CHOLERA.

Professor Peter, in a speech at the Paris Academy of Medicine a few days ago, referred to the theory that cholera was a nervous disease, and quoted the opinion of Chapman, of London, to that effect (as taught by M. Jules Guérin fifty years ago). By quieting the spasm of the blood-vessels and reducing spinal congestion, the animal heat is revived and the muscular cramp arrested. By its influence the current modifies the innervation of the great splanchnic nerves, as does the ice-bag: hence the epigastric symptoms are relieved and the prominent vomiting is controlled, as happens under galvanism in non-choleraic cases. It is probable that galvanism may supplant the ice-bag in the hands of experts, but further trial is of course necessary to establish its actual value.

ELECTRICITY IN DILATATION OF THE STOMACH.

In the *Rivista Clinica e Terapeutica*, Dr. Predazzi reports two cases of atonic dilatation of the stomach successfully treated by faradism applied for *two minutes* daily, improvement being noted in ten or twelve days. In a paper on "The Treatment of Abdominal Disorders by Electricity,"* published some time ago, the results in thirty cases were noted, and we cannot at all endorse the method here quoted. From ten to twenty minutes daily under galvanism were requisite for at least six months in our practice, and faradic currents were ill borne in every instance, the abdominal muscular contractions being too painful, yet inseparable from faradism.

ELECTRICITY IN SKIN-DISEASE.

Dr. Hardaway has remarked the wide usefulness of electrolysis in cosmetic manipulations. In hirsuties, in warts and moles, in milia, in many small fibromata, and in cutaneous horns he finds galvanism of value. He reports decided success in pigmentary defects such as very dark freckles, his method being to prick the surface at many points with a fine needle, care being taken not to go down through the corium, so as to avoid scarring. In the disfiguring port-wine marks one plan is to place over the surface a thin plate of zinc perforated with numerous holes, through which the needle is inserted, and the perforations are thus prevented from overlapping each other. Reference may be made for fuller account to the *Journal of Cutaneous and Venereal Diseases*, No. 4, vol. iii.

GALVANISM IN DIPHTHERITIC PARALYSIS.

This form of paralysis undoubtedly tends to recover spontaneously; but, in order to contrast the value of tonics, massage, and electricity, Dr. James K. Thatcher, of Yale College, submitted a severe case to experiment, in which paralysis of both arms and legs was present. Under tonic treatment, the progress towards recovery was noted in the general condition, but the arms were reserved for experiment. The strength measured by a grip dynamometer was, on beginning, right 31, left 29. Five periods of seven to ten days each were compared with each other, and the gains with faradism and massage were:

	Arm treated.	Arm untreated.
Massage	8.3	11.4
Faradism	4.3	4.1

Here massage appears to have done more harm than good, and faradism was of little use; yet one case will not do to base definite conclusions on. Less difficulty is met in the results from galvanism, which were as annexed:

	Galvanized Arm.	Untreated Arm.
1. Ten days to left arm .	17	12
2. Seven days to right arm	15	10
3. Seven days to left arm .	7.4	0.9

The galvanized arm made progress in the rate of 1.72 to 1 in the other,—nearly twice as much. The dynamometer strength now was—right 74.6, left 75.8. In our own practice we rely on central and general galvanization, without tonics or massage, and the progress is fully as rapid as that of Dr. Thatcher, with less trouble to the patient.

SEVERE ELECTRIC SHOCK.

Dr. Liman called attention to the results of lightning-stroke at a recent meeting of the Berlin Verein für Innere Medicin. Various ecchymoses and excoriations, supposed to be photographs of trees, clouds, etc., are shown to be due to protection of the surface by heavy or light layers of clothing offering resistance, and death is generally attributable to asphyxia. Rupture of internal organs is common. Prof. Leyden confirmed the opinions of Dr. Liman.

Dr. W. G. Eccleston refers to the fact that text-books say little or nothing about the treatment of shock from lightning or contact with dynamo-electric machines. He notes in the *Medical Record* three cases with extreme cardiac and respiratory depression, and he has found the hypodermic use of atropia in doses of $\frac{1}{100}$ to $\frac{1}{80}$ of a grain the best way to combat the symptoms. In these days, when one is liable at any moment to fall in with cases of severe shock from electric-lighting plants, the results of Dr. Eccleston's labor are of much value.

ELECTRODE COVERINGS.

Dr. Massey proposes the use of absorbent cotton as a substitute for the sponge

* Medical Bulletin, October, November, and December, 1884.

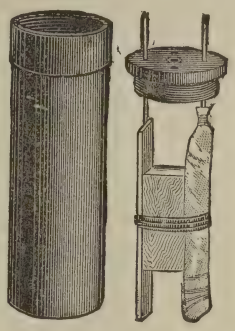
covers ordinarily employed for rheophore disks or points. The cotton is easily applied; it holds enough moisture to conduct properly; it is clean, and cannot convey any disease from one patient to another, which is a point not usually thought of by general practitioners. We have always used fresh covers of muslin for each case, held on by small rubber bands, all of which can be relegated to the waste-basket when done with. But the idea of Dr. Massey is at once simple and efficient after the knack of twisting the cotton on is acquired, at least in the smaller rheophores. In large disks, sponges will, we think, still be the better; and they must, of course, be thoroughly cleansed by boiling water and carbolic or sublimate soap after each application.

IMPROVED ELECTRICAL APPARATUS.

The ordinary portable batteries have heretofore been inconvenient and unreliable, particularly those using carbon plates and electropoion fluid, from the tendency of the carbons to break easily and of the acid to fail unless frequently replenished. In addition to this, the plates in such instruments must be lifted out of the solution when not in use: hence it is difficult to keep the cells acid-tight by the best form of hydrostat, single fluid elements are generally too weak, and gravity-cells do not suit for any except permanent apparatus. A new instrument is now made with elements of zinc and silver chloride immersed in zinc-sulphate solution.

The cells which hold the fluid and enclose the elements are of hard rubber, three inches long and one inch in diameter. A plate of hard rubber has upon its upper surface rows of protecting studs corresponding to the number of cells of the battery. To the under side of this plate are permanently attached plugs or stoppers of hard rubber, which form the caps of the battery-cells. These plugs and the mouths of the bottles are provided with corresponding threads, so that each bottle may be readily screwed to its cap or removed from it without interfering with the others.

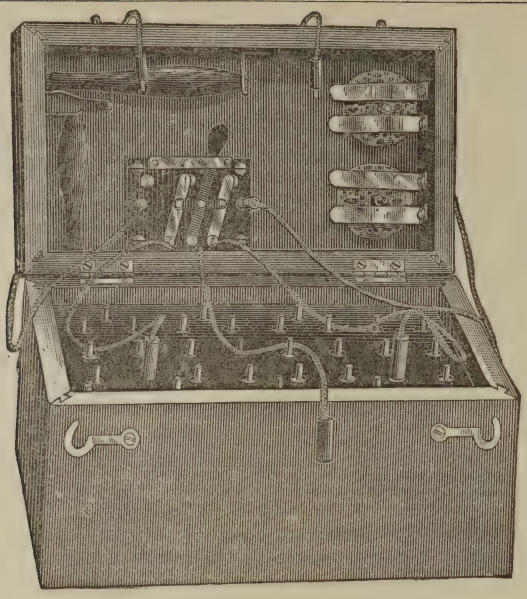
The connections are entirely free from corrosion. The silver wires, which are attached directly to the zinc and silver plates in the cells, are passed up through the caps and plate, and fastened down under nuts which screw upon the connecting studs. There are no connections underneath the plates. The nuts and ends



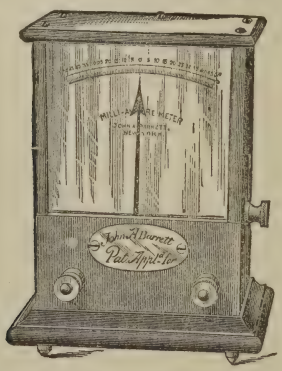
of the silver wires are on the top of the plate, easy of access, and entirely removed from moisture or the fluid of the cells.

The metallic elements of the battery are connected in order to the studs which form the terminals of the successive cells by silver wires, which pass up through perforations in the caps and plate, and are screwed down in pairs under nuts turning upon the studs. A perforated top plate of polished rubber, through which the tips of the studs project, is laid over the whole. On this plate are stamped the number of the studs in the order in which the connections of the battery are made. The current-reverser is located in the cover of the box. The wrapping around the chloride-bar retains the metallic silver formed by breaking up the salt when the circuit is closed, and this can be sold or exchanged for new plates: hence there is no waste. The zincs, it is stated, last indefinitely. The whole is compact, and, with the addition of a rheostat in the cover of the box, will be an excellent apparatus. The force is about that of the Daniell,—one and a tenth volt per cell. The internal resistance is said to be only about four ohms in thirty cells, which is very little, if true. The connections are simple; but we prefer screw binding-posts to split clamps, which are apt to lose their spring power. The cuts show the internal construction and general aspect of the battery complete.

Mr. Barrett, of New York, the maker of the battery described, has also got up a milliampèremeter for absolute measurement of constant units of electro-motive force. We have repeatedly urged this point upon our readers, for the hap-hazard method of dosage with electricity is at the bottom of



nearly all failures in using it. The usual galvanoscope simply shows the battery to be working, and tangent or sine galvanometers are cumbersome and costly,—too much so for the medical electrician. The new instrument is quite accurate: it is sensitive, yet steady, and gives units always the same for an equal force of current. As the correct way is always to employ so many volts or milliampères, instead of such a number of cells, which may or may not be uniform in strength day after day, the utility of the meter is apparent.



The instrument is the outgrowth of the effort of Dr. De Watteville, of London, to establish a unit of measurement by electricians at the Congress of 1878. The meter may be used simply as a test of current-strength before applying electricity to a patient; but the better plan is to intercalate it in the circuit during the sitting, together with a rheostat. Its internal resistance is about fifty ohms, which must be compensated for by added cells, which bring the needle to the index desired during the treatment.

STATISTICS RELATING TO SEVEN HUNDRED BIRTHS (WHITE) OCCURRING IN THE PHILADELPHIA HOSPITAL (BLOCKLEY) BETWEEN 1865 AND 1872.

BY JOHN STOCKTON-HOUGH, M.D.

THESE tables were constructed some years ago, with a view of obtaining certain facts which have from time to time been incorporated in other papers published by the author, and are now offered to the profession in their entirety for the first time.

These are the only tables I know of in which the length of the trunk of the fœtus is compared with the entire length, and from an examination of which I discovered that female children have the trunk longer in proportion to their entire length than do males,—as may be seen from an examination of the table devoted to this fact. The weight of the placenta is not given; but I have shown in another paper*

* "Influence of the Sex of the Fœtus on the Condition of the Mother during Gestation, Lactation, etc." *Amer. Jour. of Obstet.*, February, March, May, June, 1884. Reprinted, 8vo, pp. 70, New York, 1884.

that observations founded on sixteen thousand cases show the placenta to be heavier in proportion to the fœtal mass in the case of females than with males,—an explanation of which may be found in the paper referred to. The duration of gestation is shown to be longer by three days with males than with females. The duration of labor was from two to four hours greater with males than with females.

An examination of the following table shows that the duration of labor (all stages combined) is greater with male children than with female.

Table showing the Duration of Labor (all Stages combined).

PRIMIPARÆ.

Males.	Hours.	Weight. Pounds.	Ounces.	
153	20.21′	7	7.3	Single women.
54	20.36′	6	14.8	Married "
Females.	Hours.	Weight. Pounds.	Ounces.	
168	17.41′	6	13.2	Single women.
48	16.26′	6	7.3	Married "

MULTIPARÆ, SECOND LABOR.

Males.	Hours.	Weight. Pounds.	Ounces.	
17	11.03′	7	12	Single women.
44	13.30′	7	12.5	Married "
Females.	Hours.	Weight. Pounds.	Ounces.	
51	16.16′	7	9	Single women.
44	11.18′	7	7	Married "

The proportion of sexes was as follows:

Illegitimate: 170 boys to 211 girls, or 80.5 boys to 100 girls.
Legitimate: 98 boys to 92 girls, or 106.5 boys to 100 girls.

EPILEPSY DEVELOPED DURING TYPHOID FEVER.

BY CHARLES BAUM, M.D.

MARY F., æt. 14 years and 6 months, an inmate of the Soldiers' Orphans' Institute of this city, was visited for the first time January 9, 1885. She was of medium height, slender figure, and nervous temperament. Menstruation had begun five months previously, and had been properly performed. After several days of increasing languor she went to bed, where she now had been four days, with weakness of limbs, headache, drowsiness, slight fever, loss of appetite, yellow-furred tremulous tongue, repeated epistaxis, pulse 112 per minute and weak, and diarrhœa for two days, the stools having the usual ochre color. The day following, numerous rose-colored spots, disappearing upon and returning after pressure, appeared on the skin over the abdomen and the thorax. There was moderate tympany and evenly-diffused pain in the abdomen on pressure. Three days later active delirium occurred. During convalescence constipation was present, but was easily relieved.

From the onset of the attack the treatment consisted in liquid diet and the administration of dilute muriatic acid. During the second week oil of turpentine aided in cleansing the dry, brown tongue, decreasing the diarrhœa, and relieving the delirium.

Nothing of unusual note marked the progress of the fever until February 6 (four weeks from the date of the first visit). Just when she had fairly entered the stage of convalescence, and before any change of diet had been made, sudden emesis occurred, and four hours later a fully-marked epileptic fit. Spasm after spasm followed with such rapidity that at no time for the space of three hours did the muscular system become quiet. At this juncture I saw her and immediately administered ether by inhalation, which speedily arrested the convulsions. Each paroxysm was marked by double internal strabismus, widely-dilated pupils, grinding of the teeth, frothy blood-tinged saliva, fingers firmly clinched over the thumbs, and tonic, followed by clonic, muscular contractions. After the inhalation of two fluidounces of ether she fell into a heavy sleep of eight hours' duration, from which she awoke in a state of confusion. The urine was examined and found negative as regards albumen, but it contained a large excess of phosphates.

Upon the date of the fit menstruation should have occurred, but was not resumed until her usual health was regained. One week later a second convulsion occurred, being announced by a sharp cry. The entire paroxysm lasted about five minutes, and was followed by a deep sleep. Bromide of potassium with fluid extract of valerian was ordered for the epilepsy. During the following three weeks numerous (about twelve) superficial abscesses were incised.

Careful inquiry into the history of the patient did not reveal any suspicion of previous night- or day-epilepsy. Her father is said to be a peculiar man, and on two occasions, without any known reason, has abandoned his family and was not able to give a clear account of his wanderings. Her mother was delicate, and died of typhoid fever.

On two occasions, during the seven months since the first convulsion, while excited, she has had a pronounced seizure, —the so-called *petit mal.* She has been carefully watched, but as yet no attack seems to have occurred during the night.

630 NORTH BROAD STREET, PHILADELPHIA, PA.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF ARTHUR V. MEIGS, M.D.,

One of the Attending Physicians to the Hospital.

Reported by CHARLES BAUM, M.D.

VALVULAR DISEASE OF THE HEART, WITH PULMONARY APOPLEXY AND TYPHOID FEVER.

GENTLEMEN,—Before showing the interesting pathological specimens before me, I will read the history of the case:

Charles S., æt. 24, single, German, a baker, has been in this country two and a half years. His mother and sister died of phthisis. When 15 years old he had two attacks of articular rheumatism, and he has suffered from dyspnœa and palpitation of the heart for five or six years. One year ago he was admitted into this ward, suffering with acute inflammatory rheumatism and accompanying pericarditis. Endocardial inflammation was also present, there being a positive systolic murmur at the

apex, as well as a double murmur at the aortic cartilage, indicating mitral regurgitation with aortic obstruction and regurgitation. After leaving the ward he resumed baking, and in the winter spent three months grappling for oysters: since then he worked daily at his trade until two days prior to his admission to the hospital, on September 7. For the past three months he has had cough, muco-purulent expectoration, and night-sweats. Gradually he found himself becoming more weak, and for two weeks he coughed up bright blood, which has recurred daily since. He had been in bed only two days. Upon admission a thorough physical examination was not permissible, owing to his condition. The condition of the pulse known as Corrigan's or water-hammer was very marked; and, although the heart was acting tumultuously and irregularly, a loud systolic murmur was audible at the inferior angle of the left scapula. A few days later physical examination revealed pulmonary emphysema and apoplexy, and also general hypertrophy of the heart, especially of the left ventricle, as well as mitral regurgitation and double aortic disease. Five days after his admission ochre-colored diarrhœa began, followed by epistaxis, stupor, dull hearing, dry brown tongue; and several days later rose-colored spots upon the abdomen, which was very tympanitic from the onset of the diarrhœa. At this time all traces of blood disappeared from his sputa. Death occurred twenty-six days after his admission.

Autopsy twelve hours later. On opening the thorax, the pericardium was found somewhat thickened and universally adherent to the heart. The right lung was bound down by old pleuritic adhesions at its base. It does not collapse, but crepitates throughout its anterior and upper portions, but at the posterior and inferior aspect it is carnified. Greatly-emphysematous patches occupy the anterior and inferior surface of the left lung, which crepitates throughout, except at the posterior inferior aspect, where there is a large dark area of carnification; its anterior border is enlarged and did not collapse, so that it must have projected across the median line. The left ventricle of the heart is very much enlarged, both the cavity and the walls. The same condition is present in the right ventricle, but less in degree. The pulmonary and tricuspid valves are natural; the aortic valves markedly thickened, stiff, and with rounded edges; the mitral flaps are enlarged, stiffened, thick, and opaque, and the opening is enlarged perhaps one-fourth. The heart-muscles look pale and seem hard. In the small intestine, for about five feet above the ileo-cæcal valve, Peyer's patches are enlarged, and ulceration has occurred in many of them. The liver weighed four pounds, and at the anterior margin, covering the gall-bladder, there was an abscess about the size of a walnut. A calculus was found in the cavity of the abscess, having provoked suppuration after ulcerating through the gall-bladder, which was much thickened and adherent to the under surface of the liver. Within the gall-bladder a large, fragile calculus, one and one-half inches long by one-half inch in diameter, was discovered. During life there were no symptoms pointing to this condition. True, elevated temperature was observed, but this was accounted for by the condition of the lungs and the typhoid fever.

This case fully illustrates the difficulties in diagnosis where several morbid processes are present. Prior to death, emphysema, pulmonary apoplexy, valvular disease of the heart with hypertrophy of its walls, and typhoid fever were diagnosticated; while there were no symptoms pointing to adherent pericardium, abscess of the liver, or gall-stones.

TRANSLATIONS.

Syrups of Hippurates of Calcium and of Lithia.—Dr. V. Poulet recommends the following formulæ:

1. *Syrup of Hippurate of Calcium.*—
   Pure hippuric acid, 100 grammes;
   Milk of lime, sufficient to produce an alkaline reaction;
   Hot water, 2 litres;
   Sugar, 2400 grammes;
   Spirit of lemon, 15 grammes.

Add to the acid a portion of the water (at 80° C.), and then gradually the lime (agitating the mixture), until it no longer reddens litmus paper, which requires about fifteen minutes to complete the reaction; then add the sugar and expose to gentle heat, and make a syrup, which is subse-

quently flavored with lemon. For diabetic patients the sugar can be omitted.

2. *Syrup of Hippurate of Lithia.*—

Lithium carbonate,	8 gr.
Hippuric acid,	35 "
Warm water,	1000 "
Sugar	1200 "

Add a little water to the acid, and then the lithium carbonate, so as to obtain a solution of alkaline reaction; then add the rest of the water and the sugar, and place upon a gentle fire. Each teaspoonful of syrup contains twenty-five centigrammes of the salt, in which there are but three centigrammes of the base.—*Bulletin Gén. de Thérapeutique*, August 30 and September 30.

Dr. Poulet has used the lime hippurate in diseases of the bladder with alkaline urine, in liver-affections with or without jaundice, and in diseases of hot countries, which are often attended by hepatic disorder. In skin-diseases, where produced by an attendant diathesis, whether gouty, scrofulous, or tuberculous, a useful field is presented for this agent. Affections of the mucous membranes are also cited as being favorably influenced. Cases of dyspepsia, diabetes, and chronic rheumatism are especially benefited by this treatment. The lithia salt is reserved for cases having the uric acid diathesis. A case of rheumatoid arthritis with deformity of the right hand was almost entirely cured by the use of the syrup of hippurate of lithia. The lime salt the author believes to be one of the best and most efficient agents of the materia medica.

Lymphoderma Perniciosa, a New Form of Skin-Disease.—A woman, 39 years of age, came under the observation of M. Kaposi (*Wien. Med. Jahr.*, 1885), having suffered for a year with an eruption which was diffuse upon the face, head, and neck, and irregularly localized in groups or patches on the hips and extremities. It was associated with a doughy swelling and thickening of the affected skin. In the several parts of the body named there had been developed, both in the corium and in the subcutaneous cellular tissue, numerous small growths from the size of a pea to that of a pigeon's egg; some of the tumors were dense, some apparently fluctuating, not distinctly circumscribed; and when opened, spontaneously or by incision, a custard-like, purulent material was discharged. The urine contained neither albumen nor sugar, but there was an enlarged spleen and a well-defined leukæmia. The serous imbibition and thickness of the skin attained, while under observation and after a transitory improvement, a still higher development; the tumors increased in size and number, so that the woman's features were finally rendered unrecognizable: she died very suddenly after five months' residence in the hospital.

In the post-mortem examination, in the locality corresponding with the tumors the adipose layer in the œdematous cellular tissue was changed into dense whitish-red masses, the overlying skin forming a bacon-like layer, which was not entirely distinct from the growth. The microscope showed the tumor, as a whole, to be partly supplied with vessels, with a delicate thread-like stroma, with its interstices crowded with lymphoid cells and nuclei. Similar new formations were discovered in the lung, the spleen, and the bone-marrow: the lymphatic glands had the usual characters of leukæmia. The connection between the dermatosis and the leukæmic process appears unquestionable.—*Centralblatt für Med. Wiss.*, No. 40.

Hydrofluoric Acid in Therapeutics.—Dr. E. Chevy (*Bull. de Thérap.*, p. 108), after investigating the properties of this acid and observing its effects clinically, arrives at the following conclusions:

1. The vapors of hydrofluoric acid, mixed with air, do not produce the respiratory accidents which we have hitherto been led to suppose. Without inconvenience, an adult can breathe a mixture of one to fifteen hundred parts of atmospheric air.

2. Hydrofluoric acid is a powerful antiseptic and antiferment. In the proportion of one to three thousand, it arrests the fermentation of milk, of urine, or of soup, and can be used for the preservation of meat.

3. The therapeutic employment of hydrofluoric acid in pulmonary tuberculosis, in diphtheria, and in the dressing of foul wounds, has furnished results which are worthy of being followed up.

4. In a case that is asthmatic, hæmophilic, or emphysematous, it should be employed with great prudence.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, OCTOBER 31, 1885.

EDITORIAL.

MAY CRIMINALS BE USED FOR PHYSIOLOGICAL EXPERIMENTATION?

FROM time to time the intimation is given that there is much good "material" wasted in the ordinary process of law, and that crucial physiological experiments might properly be made upon condemned criminals for the benefit of science; and the argument, when viewed solely from a medical stand-point, is a plausible one. The *Indian Medical Gazette* contains an editorial urging the practice on the score of humanity, and suggesting that out of the three or four hundred criminals who suffer the extreme penalty of the law annually in India some might be obtained upon whom experiments could be made,—for instance, to decide finally the question as to the contagion or non-contagion of cholera,—offering pardon to those who survive. The men are doomed, a chance of escape is offered, science will be advanced, and humanity will be benefited.

Unfortunately for the position of the advocates of experimentation *in corpore vile*, there are several objections to it which appear insuperable. In the first place, when a guilty wretch has been condemned to death, the sentence is based upon the deliberate conviction that no less punishment will satisfy the demands of justice and outraged law; and, after searching judicial investigation, no doubt remains that a milder sentence would be inadequate to the protection of society and unsuited to the grade of his offence. Here is a dilemma. A criminal's life is forfeited to outraged law. Science asks for his body for experimentation, but evidently it can be delivered only under a pledge that the sentence of the law shall be fulfilled and that the criminal shall not be permitted to survive. But in civilized communities the condemned is protected by public sentiment and legal enactment against cruel and unusual forms of punishment; consequently the kind of experimentation that is proposed could be carried on only with the consent of the victim. Such consent, however, might be obtained by holding out the hope of recovery and freedom. Is it possible, we ask ourselves, that any could be found so utterly heartless as to approach a poor, condemned wretch with promises of health and security, and with a refinement of cruelty make use of him for physiological experimentation, and when finished, while he is still buoyed up with hopes of life, give him his death-blow with the hypodermic needle? Even could such a monster be discovered, he certainly would be denounced and his work disowned by the medical profession at large, the mission of which, in the words of Baron Larrey, is to cure, and not to kill.

It may be urged that such a promise might be made in good faith, and that the man, by a desperate chance, might escape, and while it is true that the chances would be very much against him, still he need not necessarily be killed by the physiologist. True; but, if he survive, a new and very serious question arises: What will be his future status in society? The law having declared him to be such an enemy to the community that its only safety consists in destroying him like a wild beast, and that his life is justly forfeited, how is the law to be satisfied? Can moral regeneration be secured by inoculation with comma-bacilli? Will a bad man, as the result of vaccination, or artificially induced cholera, have his nature so changed that he will become a good citizen and fit to be trusted with the ballot? What becomes of the sanctity of the law and the stability of society if a man may commit murder and escape with

the infliction of a diarrhœa, or sickness more or less severe, at the pleasure of his physiological humanitarian friends?

Without discussing the question further, we will merely say that the suggestion is impracticable and discreditable to our age and modern civilization. There was a time when condemned criminals were handed over to the doctors to be experimented upon until finally despatched with a drachm of opium. That time has passed. The world indeed moves. Truth is still earnestly sought for, but only by justifiable and legitimate methods:

"Weh dem, der zu der Wahrheit geht durch Schuld!
Sie wird ihm nimmermehr erfreulich sein."

ABDOMINAL TAXIS FOR OBSTRUCTION OF THE BOWELS.

IN the first of a proposed series of lectures upon the treatment of cases of obstruction of the bowels, Mr. Jonathan Hutchinson (*Medical Press and Circular*, October 7) advises a method of treatment which he described in a paper written a good many years ago as "abdominal taxis." This term was employed in order to distinguish it from taxis in hernia, and was intended to be applicable to certain manipulations used for the reduction of strangulated hernia within the cavity of the abdomen. Essentially differing from the conclusions of Mr. Treves at the recent session of the British Medical Association, who, in cases of acute obstruction, advocated absolute rest, and, if the symptoms do not promptly yield, early laparotomy, Mr. Hutchinson, in dealing with acute intra-abdominal obstruction of the bowel, recommends the following course: "First, the patient shall be placed in a state of anæsthesia to a full extent of insensibility, so that the abdominal muscles are all fully relaxed; then the surgeon is to manipulate the abdomen, pushing the intestines backwards and forwards vigorously as a mass; then he is to shake his patient after several strong assistants lift the patient, and shake the patient vigorously from side to side, and backwards and forwards; then he is to be held in the inverted position and vigorously shaken, so as to allow of any coil of intestine which may have been twisted having a chance of slipping back again. There are various other little details: for instance, he should be placed upon his back, with his feet on the bed, and shaken. Lastly, in these altered positions he is to have enemata given him, copious enemata, and this especially while he is inverted."

This appears like vigorous treatment,—certainly one which requires discrimination in the selection of cases. It is recommended in all cases of obstruction "in which no hernia can be discovered and where no diagnosis can be made, such as of intussusception," and where no more special mode of dealing with the cause of the obstruction can be adopted, and may be repeated daily until the patient is relieved or he passes into a condition where it is obviously useless. Full doses of belladonna are of great assistance, and in a good many cases a laxative may be judiciously used, such as Epsom salt in very small doses repeated every two or three hours.

The taxis should be resorted to, in Mr. Hutchinson's opinion, in every case of abdominal obstruction directly after it passes the limits of mere constipation and as soon as it has been made certain that the obstruction is not low down or owing to hernia. The patient should abstain from food, should receive rectal nutritive enemata, and be kept under the influence of belladonna and opium. Several successful cases are reported by the lecturer, one of which was relieved only after being tossed in the air upon a sheet, and afterwards stood upon his head while an enema was administered.

In elderly persons, where the site of the stricture is thought to be in the colon

itself, and probably malignant, lumbar colotomy is preferred to abdominal section. Where intussusception has been diagnosticated, laparotomy is advised; but the eminent lecturer thinks that the exploratory operation merely for diagnostic purposes ought never to be done. By this practice he believes lives have been sacrificed which might have been saved, and he accordingly enters a protest against early or exploratory laparotomy. In recording this opinion, however, he states that it is one which he holds subject to recantation in future years: in the further advance in surgery it may be found to be bad advice. There are some who may feel inclined to make this criticism now; but the experience and deliberate judgment of such an authority as Mr. Hutchinson are certainly entitled to most respectful consideration.

EXAMINATIONS TO BE REQUIRED BEFORE REGISTRATION.

BY the provisions of Section IV. of the Act of 1881, known as the Registration Act, the duty is laid upon the faculties of the medical colleges and universities in this Commonwealth of examining the diplomas of all persons desiring to enter upon the practice of medicine in this State by virtue of a diploma issued by any college, university, society, or association in another State or foreign country; "and the faculty, being satisfied as to the qualifications of the applicant and the genuineness of the diploma, shall direct the dean of the faculty to endorse the same; after which such person shall be allowed to register" in the manner prescribed by another section of this Act.

Hitherto the Philadelphia Colleges have merely passed upon the genuineness of the diploma, without testing the qualifications of the candidate; but, by a recent decision of the Supreme Court, the colleges must obey the literal construction of the law and satisfy themselves of the attainments of the applicant. Accordingly, Prof. Tyson, the Secretary of the Medical Department of the University of Pennsylvania, has just issued a circular announcing that "In the future, all persons desiring from the University of Pennsylvania the endorsement on the diploma demanded by Section IV. of the Act of 1881 will be required to pass an examination on chemistry, anatomy, physiology, materia medica and therapeutics, pathology and morbid anatomy, practice of medicine, surgery, and on obstetrics; failure in any branch will cause rejection."

A similar course has been decided upon at Jefferson College and the Medico-Chirurgical College, in conformity with the requirements of the law; and hereafter the Philadelphia schools will follow a uniform rule and will refuse their endorsement of any diploma, even if the genuineness is unquestioned, until they have been satisfied that the professional attainments of the applicant are at least up to the standard attained by their own students. This is, indeed, only justice to themselves, for their endorsement upon a diploma is popularly construed as being equivalent to conferring their diploma upon the applicant.

WE believe (1) that a successful and thoroughly creditable meeting of the International Medical Congress will be held in Washington in 1887.

2. That, in spite of malcontents and irreconcilables, existing difficulties will be successfully surmounted under the guidance of Drs. Flint and Davis and the Executive Committee.

3. That a way will be provided for those gentlemen who resigned under a misapprehension to return and accept the offices to which they were originally nominated.

4. That several aspiring Hamlets will be absent when the final cast is made for the play, and they will not be missed.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THE different medical schools have now opened for the winter session. The addresses were delivered on the afternoon of the 1st, and on that morning the *Standard* (which takes a good deal of interest in medical matters) came out with a leader on "Medical Education in London." From time to time I have criticised the present teaching in what some readers might regard as a hostile manner, and attribute to the fact that my early efforts to become connected with a teaching hospital were not successful,—a fact which now causes me no regret. A few quotations from the leader, which is obviously written by a man familiar with the facts, may support the position and attitude taken upon the subject.

"It requires some exercise of the imagination to trace a resemblance between the Medical Faculty of London and that of any other European centre of learning whatsoever. Nowhere else is there so little of the academical spirit, so much indifference to organization, or so little trouble taken to select and appropriate for the great purposes of professional exposition and guidance those who have the true *facultas docendi*. The reasons assigned for this second-rate position are various. According to some, it is owing to the vexatious obstacles, like so many hurdles in a race, put in the way of all but those students with the longest purses and the greatest staying power in their endeavors to crown their term of study with a University degree. Others declare it is due to the hap-hazard way in which teaching appointments in the London schools are made, and the cynical maxims about the inutility of lectures which most of the metropolitan medical teachers have come to adopt. According to yet another set of critics, the reason is that medical science has become largely an affair of the work-room, demanding well-appointed laboratories, such as the schools attached to the London hospitals cannot provide unless they join their resources for the purpose, and to that extent efface their individual existence."

The writer then goes on to consider the position of the two great medical corporations which are now talking over the prospect of a conjoint examination which shall carry with it the coveted M.D., and says, "There is no room for doubt as to the particular duties that the two royal corporations are called upon to assume so as to entitle themselves to academic rank and privileges. The work lies ready to their hand, and has so lain for a good many years past." This is rather severe upon the corporations. He then invites them to put their best foot foremost, and evolve order out of chaos, to provide and control laboratories, and the professors of various kinds in all the great subjects of study, just as they now provide museums, libraries, and examinations. "Then, and then only, will they be entitled to ask for a charter conferring academical privileges." The millennium will arrive before they are qualified to ask for these academic privileges.

The College of Surgeons has a library, a museum, and examinations; but the Royal College of Physicians has only examinations, for its library is contemptible, and museum it has none. Neither has it funds to do anything with. It is as poor as a church mouse; while the College of Surgeons recently fell heir to something near a quarter of a million by the will of the late Erasmus Wilson, of skin-disease fame. How the College of Physicians is to comply with the writer's expectations it is not easy to see. "The College of Physicians has public duties as real as in the days of Linacre, although of a new complexion. They cannot and must not decline the growing obligations which circumstances conspire to urge upon them." It may be safely averred that it will carefully "conspire" how to get out of these "obligations." It has just issued a new Nomenclature of Disease, and made a mess of the Pharmacopœia; but for any healthy purpose it has neither capacity nor inclination. Instead of its once-honored position, it has now sunk to an object of derision, into a semi-respectable dotage, from which nothing less than a miracle can rescue it.

The most important address was that delivered by Jonathan Hutchinson, F.R.S., at the Yorkshire College, Leeds. He explained that, "a Yorkshireman myself, apprenticed and educated in my native county," it was a peculiar pleasure to him to address his audience. He went on: "So far as this world is concerned, we can find perhaps no better symbol of human life than that given by an evergreen tree. The leaves are the generations of men; the root, stem, and branches the social institutions by which each successive generation is borne up into higher life. We live in the most literal manner upon the past, and are what we are in virtue of its former life. If during any one year the production of leaves had failed, if they had been found unequal to their task, the death of the tree in part or in whole must have followed, and no further outbursting of the leaves would have been possible. Upon the vital vigor of each generation has depended, in the past, the growth of the tree. They were the digesters of its sap; they prepared its wood. It is, of course, a mistake to suppose that evergreen trees do not shed their leaves: they simply escape to a larger extent the influence of season, and retain their leaves longer than others; but, as any one who has stood under a fir will know well, their leaves are constantly submitting to

death when old, and are replaced by new ones. An evergreen, therefore, rather than one which becomes bare every winter, must be our symbol, and none perhaps better than the Norway pine. Any one musing upon the magnificence of this splendid tree may usefully remind himself of the beneficence of the law of individual death. It is thanks to that law that its growth has been attained and its greenness made lasting. Each successive generation of leaves has taken up the work of its forerunners, and, 'eager to do and die,' has in turn submitted to the same fate. The result has been increasing growth and perpetual youth. There has been permanence of life amidst unceasing change. So it is in the human family." The prejudices, the narrow formularies, and the erroneous conceptions of the past fall with the dead leaves. "No process of cleansing the battered, soot-begrimed leaves of last season could compete with nature's plan, which covers the tree with new and untarnished foliage."

He went on: "The law of limitation in reference to memory is, I think, not sufficiently taken account of in education. It is most clearly the fact that the packing of our minds is like the stowage of a cargo. We cannot put in more than a certain quantity. Dexterity in arrangement will go for something, but it has its limits, and when these are reached it is impossible to put in fresh articles without displacing those already there. The busy man with his mind hurried from one topic to another, and still more those whose minds are exposed to grief, sorrow, or anxiety, will realize this, and may sometimes amaze their less-occupied brethren by their capacity for forgetting. This physical limitation in the number of our brain pigeon-holes is a fact we will do well to remember. Do what we will to improve and develop our faculties,—and we can do very much,—yet sooner or later a limit is reached, and we are then compelled, however reluctantly, to choose what we will keep and what we must surrender to the waves of oblivion." He thinks the old suspicion, that the more a man knows outside of medicine the less he knows of his own subject, is not without some valid foundation. To some may be given the power to know several things, but not to all alike.

He then discussed "knowledge" and "wisdom," and showed the latter sprang from the former. "It is only when we begin to believe in earnest that we reap the reward of knowledge. The sceptic and the half-believer must not hope for the joys of faith. The mellowing influence of creed on character cannot come to him who doubts." For those who tremble for the consequences of our giving up the Mosaic cosmogony the following words will carry comfort: "It will require several generations for us to realize the full influence of recent revelations in science. The doctrines must have been taught familiarly in childhood, their influence must have been transmitted hereditarily, before we shall be able to see what it really is. It would shake my belief in the relation between cause and effect if I could doubt that the influence of modern knowledge in reference to the history of the world and of man, and the relations of man to animals, could be other than ennobling. We shall witness from such causes an increased sense of dignity in life. Mankind will become more sincere, more earnest, more sympathetic, more hopeful, and our gain in all these respects will be the result chiefly of increased confidence in terrestrial life." He thinks that Latin and Greek may be allowed to drop out of our scholastic education, to give way to matters of wider usefulness. Even in the matter of scientific terms, he thinks "the preference of the professors of science for terms taken from the dead languages is, again, the mere survival of a bad custom, and one from which it is our duty to free ourselves as soon as possible." He thinks a great many of such terms might as well or even better be expressed in English. Pedantic words are a hinderance to the spread of knowledge. Indeed, even the learning of modern languages is too much insisted upon, he holds. He was decidedly funny in his denunciation of this educational hobby. For many persons it is highly convenient to know one or more modern languages, but for the majority this is useless. "Far better that a young man should know well the general course of French history, and be familiar with the lives of its heroes, its men of science, and its saints, that he should have followed carefully the struggles of the Huguenots and watched the long-gathering causes which led to the Revolution, than that he should know ever so perfectly the irregularity of every French verb." Whether we agree or not with all Mr. Hutchinson said, few will refuse assent to this last expression of opinion.

He continued: "What I have wished to say is, simply, that we should do our best to put a right value on things, and not waste time and labor in planting laurel-bushes in mistake for apples. Let me urge once more, and even at the risk of being wearisome, that we must distinguish between the knowledge that is fruit-bearing and that which is likely to prove barren, however ornamental or fashionable it may be." Then, with a natural eulogy of Yorkshire and some good general advice about their work, he concluded: "Do not think lightly of your own individual value in this world's work, and always think hopefully of the world's progress. The world, you may feel sure, never had a more happy day than that in which you were born. Lest you mistake my meaning, let me hasten to add that it will be happier still on the day you die; and permit me to take leave in urging the reflection that the ratio of its gain in happinesss will depend in some degree, now and forever,

upon how you live." There is much material for thought in the great surgeon's address.

At University College the address was delivered by Prof. Schaefer, F.R.S., which, as might be expected from the Jodrell Professor of Physiology, took a physiological direction. He said, "In considering the matter of education for the medical profession, we must, first of all, understand clearly what it is that the education in question is designed to attain. It is important, above all, to remember that it is education for a profession, and not for a trade, that is required; and, more than this, for a liberal and learned profession." And this is what he holds: "There should be the same acquaintance with classics and mathematics, the same knowledge of the English language and literature, of history and of geography, and of one or more modern languages, which are regarded as forming the essential elements of the education of an English gentleman." He goes on about the importance of acquaintance with Latin and Greek in a manner the very opposite of Mr. Hutchinson. He then gave a cold shoulder to school teaching of science and physiology, and quoted some most amusingly incorrect answers to sundry questions in physiology. After leaving school, the youth who would enter medicine should give a year to physics, chemistry, and biology. "To take a lad straight from school,—or perhaps to allow him first to waste a year or more bumping about on country roads in a doctor's gig, under the idea that he is thereby acquiring an insight into medical science,—and to send him to study physiology, to say nothing of pathology, without his having acquired even the most rudimentary notions of chemistry, physics, and biology, is to compel him to learn that subject without understanding it, to rob it of all the interest which it possesses, and is fatal to the future comprehension of the physical and vital problems of medicine and surgery." He then goes on to talk like a man who never felt a patient's pulse or inspected a tongue, or sat in a solitary cottage half the night with a peasant's wife in labor. Fine country doctors his ideal students would be, heaven knows. No doubt he is right in insisting upon more intimate familiarity with the subject he himself teaches; and more time might be devoted to the physiology of the digestion, even at the expense of the origin and insertions of most muscles and other "dry anatomical details, many of them of no possible application, and most of which are often forgotten after the examination in far less time than they have taken to acquire." He would have the physiological laboratory to stand on an equal footing with the dissecting-room. He clearly distinguishes between physiology and "histology." As to such a physiological laboratory he says, significantly, "Be sure it will never be done so long as the present ruinous system between the London medical schools continues." He then criticises the present teaching of materia medica, and condemns it in no measured phrase. He said, "Both in teaching and in examinations the subject ought to be shorn of its preposterous proportions and reduced to its legitimate level." He then said, "Amazing as it may sound to a Continental reader, there is not a genuine pathological laboratory attached to a single medical school in this great metropolis. The only pathological laboratory I know of in London is that belonging to the Brown Institution, which institution, I may inform the intelligent foreigner, is a dispensary for dogs."

As to that department of physiology, the action of medicinal agents upon the living body, he says, "Probably not a single room is set aside for the carrying on of private research. Certainly there will not be found any means of enabling the intending medical man to study the action of those drugs which he is afterwards, often blindly and fortuitously, to experiment with upon his unfortunate patients."

As to examinations, he thinks the best plan would be to see how to do without them altogether; but, unfortunately, he does not see how this can be done. He thinks that the large sum bequeathed by the late Erasmus Wilson to the College of Surgeons ought to provide the expensive laboratories required for the proper teaching (in London) of medicine. "And why should not London obtain what other cities and towns find no difficulty in obtaining?" Why, indeed? There is something wrong somewhere.

At St. Mary's Hospital Mr. Pepper gave the address. He, too, was on the same string,—"The tension which at present exists betwixt medical education and the examinations." He did not approve of the London University lowering its standard in order that ordinary students should get an M.B. easily. He was in favor of a teaching university for London. If the medical corporations had any real "go" in them, they would do something after all the exhortations they received. He thought it possible to give an interest to otherwise dry anatomical details. "The action of the superior oblique muscle of the eye, as learned at lecture, was to the student of anatomy a mere fact and nothing more; and a few days would probably suffice to free his memory from a burden imposed neither by choice nor desire. But who would or could forget the bewitching lines of Longfellow?—

> "'She gives a side-glance and looks down.
> Beware! she is fooling thee.'"

Certainly, if Mr. Pepper can lecture on anatomy after this fashion, he will soon become even more popular than he is at present.

J. Milner Fothergill.

NEW YORK.

THE mortgage on the property of the Academy of Medicine has now been entirely paid. The announcement of this fact at the last meeting of the Academy was greeted with applause, and well it might be, for perhaps no other medical association in this country has risen to a higher position of usefulness in scientific and educational work, or commanded greater respect or exerted greater influence at home and abroad. While it has occupied a position of dignity, it has not been so aristocratic or exclusive as to cause any physician, however humble, to feel that he was not welcome to the use of the library or to profit by listening to the reading of papers and their discussion. The Academy has been having a large increase in its membership, which tends both to widen its usefulness locally and to add to its funds. The tendency of recent years to multiply medical societies, particularly in special branches, is perhaps nowhere more striking than in New York City. It is the plan of the Academy to have Sections in the principal departments of medicine. Heretofore this plan has been carried out only to a limited extent, but it is now receiving new life. In addition to the Sections already in operation, the organization of the Section in Surgery, with Dr. Stephen Smith as Chairman and Dr. Judson as Secretary, was announced at the last meeting of the Academy.

The question would probably suggest itself to all, Will this creation of Sections result simply in an increase in the number of medical societies in the city (of which we already have enough), or will the private societies now in existence become incorporated with the Sections of the Academy? If the latter event come to pass, it may prove an advantage to the profession in concentrating its forces and in presenting it as a united representative body which will exert a higher and a greater influence over the public, especially in matters of sanitation. But all probably would not feel convinced of the possibility of such a union, nor of its advisability. It might be claimed that generous rivalry would be an advantage as an incentive to scientific effort. Again, those who have risen to eminence in their profession, or have attained success financially, might feel at home in the select company of a few, while they would not care to appear in a general society among strangers. A man with an established reputation in the profession might lose nothing by being absent from a meeting or by not taking part in the discussion, while, if he should take part and allow his name to go on the records, some little-known men might seek prominence by having their names associated with his in debate. All medical men, even those who are most ethical, know that success depends upon reputation, and that there can be no reputation for one who is unknown. Consequently all desire a wide and a good reputation, but they wish to avoid dubious methods of making themselves known, such as by vulgar advertising and mention in the daily press. The physician who does a consulting practice is dependent largely upon his professional brethren, and his reputation is spread through mention of his name in medical literature and in connection with hospitals and other public institutions. When his reputation is once fully established in a certain branch of medicine, he will always be expected to take part in the discussion of any topic pertaining to that department, and he may prefer to associate only with those who have an equally well established reputation.

It is to the credit of our profession that its members generally do not take part in a discussion unless they have something of value to say; but now and then we meet with those who gain the reputation of being chronic talkers because of an apparent resolution always to say something in order that their names may enter the journals. Some of the private societies require of their members in turn to read a paper upon some subject, thus insuring good work at every meeting by prominent men. It would not, of course, be desirable to make such a rule in a general society. Again, societies from which any member of the profession in good standing would not be excluded might fall into ruts, or become governed by a clique. We have seen examples of this sort. Whether or not any of these facts would offer themselves as objections to merging the special societies into the Sections of the Academy, it is true that the officers of the Academy have strengthened their position by obtaining, as chairmen of Sections, generally those whose scientific work has given them an enviable reputation. The intention to keep the Academy an exclusively scientific body, if carried out, will secure it against the dangers of medical politics.

While on the subject of the Academy, I might add that the President has extended an informal invitation to the members and their friends to be present at his house on the evening of October 29. I might also say that the late President, Dr. Fordyce Barker, who had been ill, at last accounts was convalescing and able to go about.

The reports of the Board of Health have recently contained from one to four cases of smallpox weekly, but we have not yet had the outbreak which has been feared in view of the epidemic at Montreal. It is safe to say that we will not be afflicted with either cholera or yellow fever, at any rate before the return of summer.

The first fall meeting of the New York County Medical Association was held Monday, October 19, Dr. C. A. Leale, President. Dr. Frederic S. Dennis read a paper on "Fracture of the Patella," and showed illus-

trative cases of treatment by wiring the fragments. The treatment advocated was that of wiring the separated bones under strict antiseptic precautions, thoroughly cleansing the limb with soap and water and bichloride solution, and irrigating with the bichloride solution (one to three thousand) during the operation, the dressings being also antiseptic. Statistics since 1883 showed this operation to be almost free from danger to the life of the patient. Suppuration did not occur, union of the fragments of bone took place, as did primary union of the soft parts, and it was safe to allow the patient to be up on the third week. But it would be criminal for one to wire the fractured patella if he did not believe in antiseptics and should fail to carry out every detail of the method in a faithful manner. Dr. H. M. Biggs then showed the micro-organisms of osteomyelitis, and the President exhibited some nummulites from the foundation-stone of Cleopatra's Needle in Central Park. Dr. Faure, lately of the French navy, was introduced, and exhibited a serre-nœud of which he was the inventor. Dr. Gouley regarded it as the best instrument of the kind which had been made, and thought it would be especially useful to ovariotomists in exerting constant traction upon the ligature applied around the pedicle, tending to tighten it. R. C. S.

NEW YORK, October 21, 1885.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA ACADEMY OF SURGERY.

A MEETING of the Philadelphia Academy of Surgery was held October 5, 1885, Vice-President Dr. R. J. Levis in the chair.

FOREIGN BODY CAUSING VESICAL CALCULUS.

Dr. J. Ewing Mears: I desire to present to the Academy a urinary calculus removed from a patient in St. Mary's Hospital three weeks ago. The patient was a man from the interior of the State, 56 years of age, who had been suffering with bladder-trouble for nine months. There had been difficult micturition, with pain, and the diagnosis of inflammation of the bladder had been made. Six months ago, in order to relieve the difficulty in passing water, he said that he had introduced a straw some two or three inches long. He was under the influence of liquor at the time, and the straw slipped from his grasp and entered the urethra. His symptoms then became more marked, and he came to this city. I introduced a sound, and discovered in the bladder the stone or mass which you see. The urine was carefully examined, and it was found to contain a large quantity of albumen and also phosphatic deposits. The question arose, in view of the man's habits, his age, and the condition of the urine, whether it would be better to perform lithotomy or lithotrity or litholapaxy. Under the circumstances, I considered lithotomy the preferable operation.

I cut the man, and in so doing opened an abscess in the prostate, evacuating about an ounce of pus. I then entered the bladder and removed this cluster of calculi with a scoop. The bladder was then washed out, and in two weeks the man returned to his home with the wound entirely closed. At the end of this time, examination of the urine showed that its character was greatly improved.

It was certainly fortunate that section of the perineum was decided upon. The abscess was not recognized before operating, although exploration of the perineum was made. There was no pain, no swelling, and no tenderness.

The question arises in such cases as this, where the age of the man, his habits, and the composition of the urine indicate serious vesical and possibly renal disease, whether it is better to perform lithotomy or the crushing operation.

Dr. Levis: How would the introduction of a straw account for this fimbriated character of the mass? If a head of wheat or barley had been passed, it might explain it.

Dr. S. W. Gross: Close examination will show that this is a spear of some grain, and that these little calculi are formed around the hairs of the grain.

Dr. Nancrede: Could not the albumen in the urine come from the abscess in the prostate?

Dr. Mears: It did not seem possible that the abscess communicated with the bladder. When I opened the abscess, I at first thought that it was connected with the bladder; but further examination showed that such was not the case. The abscess might have been due to the impaction of one of these little masses in the duct of the gland, for I neglected to say that he had passed a number of these masses through the urethra.

EXCISION OF THE SCAPULA.

Dr. John Brinton: I have a specimen which I removed on Saturday last. It is of a good deal of interest: first, from the character of the tumor, and, secondly, from the magnitude of the operation required for its removal. The operation consisted in the removal of the entire scapula, performed on a girl of eleven years of age for a formidable tumor. I may say here that the operation was unsuccessful so far as the life of the child was concerned, as the patient sank rapidly from shock, and died an hour after the termination of the operation.

The history of the case is simply this. A little girl, 11 years of age, living in the interior of the State, while playing under an apple-tree growing on a declivity, caught hold

*

of one of the branches and swung herself. The branch gave way, and she fell backward, rolling some six or seven feet, and striking the scapula upon a little projecting edge of stone. The pain from this continued for about an hour and then passed away, and there was no more trouble until last April, when she began to complain of pain over the right infra-spinatus fossa of the scapula. About the latter part of May or the early part of June swelling made its appearance, and gradually increased until the tumor assumed formidable dimensions. At the time I examined it, the base of the tumor measured fifteen inches in circumference, and the general thickness of the shoulder was four or five inches greater than on the opposite side. The child was suffering greatly. The pain during the daytime was somewhat paroxysmal, but during the night it was almost continuous. For a number of nights she received from ten to fourteen drops of laudanum to give relief. During the night preceding the operation she was carried in a chair, to give her as much rest as possible.

The case was seen in consultation, and the diagnosis of rapidly-growing sarcoma was made. It evidently involved the whole dorsum scapulæ. After looking up the statistics of the operation, I decided to attempt the excision of the whole scapula. I ought to state that the parents were fully apprised of the nature of the operation, and all the parties concerned accepted the risks, owing to the urgency of the case.

On Saturday last the child was etherized, and, beginning at the point of the acromion process, I made an incision, carrying it to the posterior edge of the scapula. The incision was not at first carried the entire length, because I wished to divide the acromio-clavicular articulation as soon as possible. The idea was to save every drop of blood that could possibly be saved. I had gathered from the reports of cases that the great peril was from hemorrhage. I therefore commenced with a moderate incision, so as to divide the acromio-clavicular articulation. The incision was then swept across to the posterior portion of the bone. An incision was next made at right angles, and the incision (somewhat curved) was carried below the angle of the scapula and the four flaps dissected up. Then I commenced at the upper part of the bone, dividing the muscles, and then passed slowly down, dividing the muscles,—taking the precaution, where there was any chance of considerable hemorrhage, to include the mass of muscle within a ligature before dividing it. Where there was no danger, a mass of tissue was grasped between two large forceps, such as I formerly used for the extraction of bullets. The incision was then carried along the posterior border and the muscles divided; it was next carried under the inferior angle of the bone and the parts raised. The incision upon the anterior costa of the scapula was carried up, the vessels being compressed; and thus, the parts being lifted, I opened the capsular ligament and turned out the head of the humerus. I next divided the heads of the muscle attached to the coracoid process. I had already divided the muscles along the spine. The bone was then readily lifted up, and the hemorrhage was comparatively small. Performing the operation in this way, only one or two vessels required ligature after removal of the bone.

Examination of the tumor shows that it consists of two portions; that upon the dorsum has been incised, and my finger goes directly to the bone, which is entirely destroyed, showing that the growth sprang from the periosteum. In examining the case before the operation, Dr. Gross and myself noticed a mass inside of the axilla. I then thought that the mass must depend upon a prolongation of this mass of morbid structure. It, however, depended upon a mass of tissue developed from the venter of the bone. These masses are continuous at the junction of the upper and middle thirds of the inferior costa. It was the posterior mass which projected into the axilla. This lifted the scapula from the chest and increased the apparent size of the tumor on the dorsal surface.

Statistics show that the mortality following the operation is greater where a portion of the bone is left than where the entire bone is removed. In forty cases of entire removal, the mortality was twenty per cent.; after partial removal, twenty-one or twenty-two per cent. Where the scapula was removed after amputation of the arm, the mortality was twenty-four per cent.

The microscopical examination of this growth by Dr. Longstreth shows that it is a well-marked example of round-celled sarcoma.

One other case of complete excision of the scapula was performed by Professor Agnew some years ago. The patient died in a short time from shock. Two partial operations were performed by the late Professor Gross.

Dr. R. J. Levis: Once, when contemplating an operation of the same kind on an adult with a large tumor,—an operation which I did not perform,—I determined upon an expedient to prevent severe hemorrhage. That was to tilt out the scapula and apply Esmarch's bandage around it, enclosing the axillary artery high up. To prevent slipping, a bandage was to be placed in front, under the rubber tube, drawing it to the opposite side.

Dr. J. Ewing Mears: We would not expect much hemorrhage from a tumor which seems, as this does, to be, as it were, enucleated. In this case the muscles are not attached to the growth. Where, however, there is a malignant growth which infiltrates the tissues and

envelops the ramifications of the blood-vessels, the bleeding may be severe and prove fatal.

I would ask Dr. Brinton if, when he turned up the mass towards the axilla, he brought into view the axillary vessels.

Dr. Brinton: I did not. I saw the subscapular artery and nothing else.

Dr. Mears: I refer to that point for this reason: that in some cases, where the growth involves the entire arm, it is necessary to extirpate the scapula with a portion of the clavicle, and also the entire arm, and it has seemed to me that in such cases it might be possible, by tilting up the scapula, to reach the axillary artery and surround it with a ligature before amputating the arm. I have not found this method of controlling hemorrhage prior to disarticulation referred to.

In considering the mortality-rate after excision of the scapula, it is desirable to consider the causes for which the operation is performed. It has been performed for necrosis, for gunshot injuries, and for tumors such as enchondromata, sarcoma, and malignant growths. In necrosis of the entire scapula, where the disease is of some duration and where there is great inflammatory thickening of the periosteum, removal of the scapula is comparatively easy. An incision made along the spine to the posterior border and then continued along the posterior border will enable the operator to lift the periosteum with an elevator periostome or the handle of a knife. In that way the muscular attachments may be severed. Such an operation gives a better mortality-rate than do operations for malignant growths, and, if I remember correctly, better than for operations for the removal of portions of the bone in compound comminuted fractures, the result of gunshot injuries.

Dr. Brinton: In this case there was no difficulty in compressing the subclavian artery with the finger. This was done by Dr. Hearn. In some of the reported cases the pressure has been made directly. In some of these cases, as soon as the acromio-clavicular articulation has been severed, the coracoid process has been broken and pressure made directly upon the artery.

Dr. Levis: Did the patient seem much depressed by the anæsthetic?

Dr. Brinton: She came from under the ether very well.

Dr. Hearn: The child was never thoroughly anæsthetized at any time. I do not think that the anæsthetic had anything to do with the fatal result.

CONGENITAL MALFORMATION OF THE COLON.

Dr. Charles B. Nancrede: I have here specimens of some little interest. They are the terminal part of the rectum and the caput coli, which were removed from an infant 50 hours old. The child had been delivered with instruments, and seemed to be in perfect health until the second night, when the nurse sent for me and said that there was something wrong,—that the child was crying and straining, but had not soiled any napkins.

On examination, I found a well-formed anus, into which I could introduce my finger one-third of an inch. It was a female child, and I could therefore make a thorough examination; but I could detect no bulging at any point. As it was twelve o'clock at night and the distention was not great, I gave an opiate, and the next morning at eleven o'clock Dr. Ashhurst met me in consultation. Neither of us could feel any bowel, but we thought it right to make an effort to reach the bowel. I dissected along the hollow of the sacrum up to the promontory, but could not feel the gut. We then decided to perform the operation in the right inguinal region, and I opened what I supposed to be the sigmoid flexure; but it proved at the post-mortem to be the caput coli. As soon as the peritoneal cavity was opened, about an ounce of serum escaped, and with it the right Fallopian tube, which was intensely congested. There was marked peritonitis. The child lived four and a half days after the operation. The meconium passed freely, and afterwards the discharges were natural. The child died from exhaustion, evidently due to the peritonitis.

The post-mortem showed that if I had detected the bulging bowel, which I must have felt, as it was near the end of my incision, I should almost inevitably have cut through two layers of peritoneum. There was a space about as wide as a director where the bowel was not covered by peritoneum, and I should have left behind the peritonitis. The question arises in these cases, if peritonitis does set in so early, and if death results, as it usually does, from peritonitis, whether it is worth while to add the double danger of two operations, especially in female children where it is impossible to detect any sign of the bowel.

Dr. Levis: Does Dr. Nancrede think well of operating before the sac becomes distended?

Dr. Nancrede: Unless something is done, the patient dies early. I notice that Bryant has called attention to the fact that peritonitis sets in very rapidly, and that in true obstruction death is frequently due to peritonitis. In this case the peritonitis was very marked at the end of fifty hours.

Dr. Levis: I have never done any operation except in the fundament. I would not like to save a child's life with an anus anywhere but in the fundament. I have always been able to find the sac and to bring it down and stitch it to the skin.

Dr. O. H. Allis: At the post-mortem, how far were the two blind sacs from each other?

Dr. Nancrede: I should say about an inch. I must have touched the bowel with my finger, but did not recognize it. Bryant strongly

advocates the operation in case of deficient rectum, and the opinion of a man who has had such an exceptionally large experience in the surgery of the bowel in general, having reported eighty-two or eighty-three colotomies, ought to count for a good deal. There seemed to be no more difficulty in retaining the fæces in this case than where the anus is in the normal position. Sometimes hours would pass without anything coming. In this case I think it would have been impossible to bring the bowel down and stitch it.

TREATMENT OF CARBUNCLE.

Dr. James Collins: I have lately treated two cases of carbuncle on the back of the neck by a method which seems to have some advantages. The patient is put under the influence of an anæsthetic, and a linear incision made. I then take a scoop and remove all the necrosed tissue, and wash the parts thoroughly with an antiseptic solution of mercuric chloride. I then put in a drainage-tube, and insert two stitches to bring the central part together. Each day the cavity is thoroughly washed out with the antiseptic solution. The patients have done well, and the cicatrix has been less than after any other method I have tried. The success depends upon the removal of the necrosed tissue and the use of the antiseptic solution.

Dr. S. W. Gross: The plan of Dr. Collins is, I think, based upon proper principles. I consider it far the best operation yet suggested. By scraping away all the dead tissue he gets rid of the micrococci which produce putrefaction, which give rise to the sloughs. The application of the corrosive sublimate destroys the micrococci which line the walls of the cavity, and in that way removes the cause of the disease.

Dr. Mears: I would ask if Dr. Collins, in scooping out the dead tissue, found anything like a thickened wall limiting the mass to be removed, and if he was able to satisfy himself that he has removed all the dead tissue.

Dr. Collins: I keep on scooping out until I reach a denser structure. The difference seems to be in the denseness of the tissue. The healthy tissue seems to be firm.

Dr. Levis: The operation of excision of carbuncles in their incipiency has been repeatedly advised and practised. In cases of constantly-recurring carbuncle I think that excision would be of service.

Dr. Hunt: I have been trying to recall a case of carbuncle on the back of the neck of a woman. I cannot recall a case. I would ask if this is the experience of the other members, and, if so, what reason can be given for this peculiarity.

Dr. Collins: I remember one severe case.

Dr. Levis: I cannot recollect a case.

Dr. Nancrede: I have seen a fatal case in which the carbuncle was on the side of the neck of a woman.

NITROUS OXIDE GAS IN THE EXAMINATION OF FRACTURES.

Dr. J. M. Barton said: I was obliged, during the last three months at the German Hospital, to examine an unusual number of fractures under an anæsthetic, as many of them were near the larger joints, and the character and extent of the bony lesion could not otherwise be appreciated. In the neighborhood of the ankle-joint alone, out of a large number examined, there were sixteen cases in which fractures were found. In many of these cases the line of fracture is quite transverse, running through one or both malleoli, but owing to the spasmodic contraction of the muscles the parts are held firmly in place, and without an anæsthetic it would be difficult to say that any bony lesion existed.

With ether many patients struggled so during the period of excitement that I often feared they might seriously complicate the existing injury. Indeed, the struggles of some of them were so threatening that I treated several cases without having administered an anæsthetic, preferring to take the risk of not fully knowing the extent of the injury rather than that a simple fracture should become compound while making the examination.

Early in March I obtained for the hospital, from S. S. White & Co., an apparatus consisting of an iron cylinder containing one hundred gallons of liquefied nitrous oxide gas, a gas-bag of seven and one-half gallons' capacity, and the necessary tubing, mouth-pieces, etc.

On March 6 the gas was administered to Marie B., æt. 26 years, servant-girl by occupation. She became fully unconscious without any struggling whatever. Fractures of the tibia and fibula were discovered, and their lines fully recognized and noted. The recovery from the gas was, of course, prompt.

March 16. Hugh C., æt. 53, laborer, a stout Irishman of probably bad habits, and whom I should have expected to struggle violently under ether. He took the gas quietly and without a struggle. I made a full and careful examination. Both the tibia and fibula were fractured. The line of fracture was fully recognized and noted.

March 21. M. S., æt. 22, baker. Had ingrowing toe-nails. Both sides of both great toes were removed under "nitrous oxide," Dr. Rehfuss, the resident physician, operating upon one toe and I upon the other. The patient stated that he had not felt a particle of pain.

March 23. Anton C., æt. 38, wagon-builder, was examined under "the gas." A comminuted fracture of the tibia was discovered, and the position, size, and obliquity of the pieces noted. In addition, a fracture of the fibula at the junction of the lower and middle thirds,

and another just below the head, were discovered.

March 27. Ellen S., æt. 42 years, servant, was examined under nitrous oxide, and a Pott's fracture found.

During this time, in private practice, I refractured a radius in the case of Miss L., using nitrous oxide as the anæsthetic. The patient was fully unconscious, and I had no more difficulty than if ether had been used.

I would call the attention of the Fellows mainly to the advantages of nitrous oxide in the examination of fractures. Its advantages in all minor operations, of course, are familiar. That it does not cause nausea or vomiting, even if the stomach be not empty, the slight risk, the immediate recovery, permitting the patient to attend at once to his usual vocations, etc., are well known; but in fractures we avoid that period of excitement which appears during the administration of ether, and during which the patient is so likely further to injure the fractured limb.

The period of full anæsthesia is from one to two minutes, but the period of total muscular relaxation is nearly four minutes.

While the anæsthetic is being administered the injured limb is fully exposed and held by the surgeon. Before the patient is quite unconscious the surgeon feels the limb become limp and lax in his hand; all the muscles are relaxed. The examination can now begin, though the patient gives some slight evidence of feeling pain. This period, the period of total unconsciousness, and the succeeding period of muscular relaxation, give about four minutes, which I have found to be abundant time to examine almost any fracture.

Nitrous oxide has been but little used in surgery, owing to the difficulties of keeping and transporting it; but the apparatus which I show you here, and which is furnished at a moderate price by the dental supply depots, overcomes these objections, and I am sure it will be found of service in many minor operations. I am well aware that some of the Fellows of the Academy have used this anæsthetic for a long time and have had great experience in its use; but I also know that very few, if any, of the hospitals use it, and it is not nearly so much used in surgery as it should be.

Adjourned.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, SEPTEMBER 24, 1885.

The President, E. O. SHAKESPEARE, M.D., in the chair.

DR. WILLIAM OSLER presented specimens of

TÆNIA ECHINOCOCCUS.

This rare parasite was reared experimentally by feeding a dog with hydatids from the liver of a pig. The animal was killed about seven weeks after the feeding, when the small intestine was found to contain many hundreds of the mature tape-worms. The portion of bowel exhibited had many adherent to the mucous membrane. From the small size of the worms, only a few lines in length, they are very apt to be overlooked. Cobbold states that the only specimens procured in England have been experimentally reared. Dr. Leidy has never met with the adult worm in this country. That it must occur here in the dog is very evident from the frequency with which echinococcus cysts (the larvæ) are met with in the hog and other animals.

CYSTICERCUS CELLULOSÆ.

Dr. OSLER exhibited the heart, brain, and a portion of the flesh of a pig containing the "measles," as the larvæ of the tænia solium are called. Both organs were thickly studded with the cysts, which are also very numerous throughout the muscular system. The animal was fat, and had seemed to suffer very little inconvenience. Attention was called to the cysts beneath the tongue, and to the possibility of telling whether an animal was measled by an examination of this part during life. Microscopic slides of the parasites were shown, and a slide of a cystocercus, with a very large caudal vesicle, from the omentum, in which situation they may grow to the size of a walnut.

DISTOMA HEPATICUM: EFFECTS ON THE LIVER.

Dr. OSLER also showed the liver of an ox, with enormous enlargement of the bile-vessels and calcification of their walls due to the chronic inflammation excited by the presence of the flukes. The main ducts were thicker than the thumb, and even the smaller tubes were hard as the stem of a clay pipe. The liver-substance was wasted, but not cirrhotic. In spite of this extensive disease, the animal was well nourished. Specimens of the flukes in spirit and mounted were also shown.

Dr. WILLIAM PEPPER presented before the Society the specimens of

TÆNIA FLAVO-PUNCTATA

described by Prof. Leidy in the *American Journal of the Medical Sciences* for July, 1884. This species has never but once before been seen and recognized, and then by Weinland, of Boston, in 1858. Both specimens were expelled from young children, and averaged twelve inches in length.

Dr. PEPPER also presented the head and neck of a specimen of

TÆNIA MEDIO-CANELLATA.

It occurred in a young man. A course of starving followed by castor oil and pelletiérine removed a portion of the worm; afterwards a repetition of the starving process, without the castor oil, but with the alkaloid, brought away the entire worm dead.

Dr. Pepper said he was particularly interested in this series: it spoke forcibly of the necessity of studying comparative pathology. The specimens were very perfect, and more instructive than more highly organized species. In practice, he had found the tænia mediocanellata as difficult to expel as the tænia solium. The exhibition of the small variety, the flavo-punctata, taught the necessity of careful examination of the stools.

Dr. De Schweinitz exhibited the kidneys, ureters, and bladder from a man who died after the operation of

LITHOLAPAXY.

The patient, æt. 73, had for two years previous to the operation suffered with straining during the act of micturition, and other symptoms of hypertrophy of the prostate gland and vesical calculus. The urine contained albumen, pus, epithelium, and granular casts, and had a sp. gr. of 1.018. The patient's habits were intemperate. The operation of litholapaxy was performed, marked difficulty having been experienced in the introduction of the instruments.

After the operation the patient exhibited great restlessness, præcordial pain, and a rapid, feeble pulse. Later he became comatose, and died twenty hours after the operation, the immediate cause of death being apparently the formation of a heart-clot.

The post-mortem examination was made about ten hours after death:

Body well made; nothing of note anteriorly; the usual ecchymoses posteriorly.

Thorax.—Old pleuritic adhesions on the right side; left side free. Lungs crepitant, with slight posterior congestion. Heart surrounded with fat; muscular fibres flabby; valves normal; firm "chicken-fat" clot with right ventricle.

Abdomen.— Position of viscera usual. Marked deposits of fat in the omentum. Liver slightly enlarged, soft, but otherwise normal. Both kidneys granular and containing cysts. Bladder thickened, and showing two spots of ecchymosis on the mucous surface. Prostate enlarged; other organs normal. Brain and membranes not examined.

DISCUSSION.

Dr. Tyson thought this case added one more to the list showing the impropriety of crushing for stone when kidney-disease was present. He did not know why, but under such circumstances the cutting-operation was more suitable. Dr. Tyson cited the case of Louis Napoleon as an instance of the danger of crushing in the presence of kidney-disease. Dr. Tyson said, in answer to a question of Dr. Barton's regarding the kidneys, that they were contracted, though not markedly so, as there was good secreting structure left. The cysts were part of the pathological anatomy of granular kidney. He believed the cause of death to be uræmia.

Dr. G. G. Davis said that in such cases a post-mortem examination was in reality of the nature of an investigation. Death might be due to direct violence done the urethra, the prostate, or the bladder; or it might be due to extension of inflammation to the peritoneum, or to unknown cause, as in the present case.

Dr. De Schweinitz said that the urethra was not examined, and agreed with Dr. Tyson that the cause of death was uræmia. This was the more probable because an officious attendant, against orders, had administered rather full doses of morphia.

Dr. Henry Beates presented a specimen of

SYPHILITIC ABSCESS AND NECROSIS OF THE TIBIA REMOVED BY AMPUTATION AT THE MIDDLE OF THE THIGH.

The patient was a strumous man, who, three years previously, had suffered from an attack of obstinate sciatica, accompanied by a marked degree of muscular atrophy of the affected limb, followed by lameness. Two years later a swelling developed at the femoral side of the gluteo-femoral crease, which opened and discharged small fragments of necrosed bone. The sinus was finally healed, and fair health enjoyed for several months. Seventeen weeks ago osteitis of the tibial head developed, followed in a short time by suppurative synovitis. The pus perforated the ligamentum posticum and burrowed beneath the gastrocnemius, elevating it and the posterior tibial muscular structures from the bone. Free incision evacuated this, but the destructive process continued, resulting in the formation of sinuses and complete disintegration of the joint. Hectic was pronounced, and to save life amputation was performed on the day previous.

Longitudinal section through the femur-joint and tibia discloses the extensive destruction effected in so comparatively short a time. The articulating surface of the condyles is denuded of its cartilage, and the surface of the bone is roughened. The patella is bound firmly to the trochlear portion of the condyles. The articular elements are destroyed. The head of the tibia is completely necrosed and broken down. The medullary canal of the tibia throughout its entire extent is infiltrated with pus. The surface of the bone is also the seat of the morbid process. The pus from the joint has burrowed upward beneath the internal and external vasti muscles, and deprived the femur of its periosteum for a considerable distance. The anterior face of the tibia is similarly denuded, while the crest at the middle is the seat of ulceration. At the time the disease occurred, the patient first noticed a chancre. Six weeks later the secondary phenomena developed, and were

promptly met with antisyphilitic remedies. Was the strumous disease influenced by the syphilis?

The specimen was referred to the Committee on Morbid Growths for microscopical examination, with instructions to look for tubercle-bacilli and for those said to be peculiar to syphilis.

DISCUSSION.

Dr. DAVIS was desirous of knowing if the disease of the head of the tibia was due to scrofula or syphilis: the worm-eaten character of the ulcer on the tibia looked like syphilis.

Dr. CHARLES M. WILSON inquired if there had been fevers, rigors, and evidences of pyæmia in this case. It was undoubtedly one of osteomyelitis, and in a similar case of traumatic origin which he had exhibited rigors had been present.

Dr. JURIST asked how the presence of acute syphilis in the patient would affect the prognosis of the operation.

Dr. BEATES replied that there had been symptoms of septic fever, and, as the acute symptoms of syphilis had been absent for some weeks, he did not think this would mar the prognosis.

DEATH FROM ŒDEMA OF THE GLOTTIS.

Dr. LOUIS JURIST presented the larynx and trachea removed post mortem from the body of a man, æt. 38, a book-keeper, who had suddenly died. He had not had syphilis. He had taken cold on Saturday and had a sore throat; on Tuesday he chatted with the doctor, and an examination gave no evidence of anything except ordinary pharyngitis; on Wednesday he went to his business; on the evening of that day the doctor was sent for in haste, and, on going at once, found the man dead. Nevertheless, a hurried laryngotomy was done and efforts were made to restore the heart, but without avail.

Dr. Jurist removed the larynx through the thoracic cavity. He was in doubt as to the mode of death. The lungs were fairly healthy, though cheesy on one side. There must have been an abscess present.

Dr. TYSON was surprised that marked improvement should have followed the treatment by emetics and sedatives, as the abscess must have been present: perhaps the outlying œdema was subdued and the condition thus improved.

Dr. WHARTON had not had experience in such cases, but agreed with Dr. Jurist that the operation of tracheotomy, and not laryngotomy, was indicated.

Dr. JURIST was in doubt in regard to the diagnosis: it rested between perichondritis and a subsequent abscess or phlegmonous laryngitis. He was inclined to the former view.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held October 14, 1885. GEORGE F. SHRADY, M.D., President *pro tem.*, in the chair.

MELANO-SARCOMA OF THE FACE.

Dr. JOHN A. WYETH presented a woman, aged 70 years, who had noticed a little tumor upon the left side of the face several years ago. It finally began slowly to enlarge, and four years ago was treated by an escharotic of some form, which left a scar and depression. Recently Dr. Fox saw the patient, made a diagnosis of melano-sarcoma, and sent the patient to Dr. Wyeth for operation. The incision extended from upon the nose an inch and a half outward upon the cheek, and a quarter of an inch below the palpebral border. The gap was filled in by integument drawn over the malar bone. Union took place by first intention and showed a very good result; there was no ectropion. The operation had been done two weeks ago. The points of interest were, the comparative rarity of the disease, and the fact that it illustrates the great vitality of the tissues of the face, and the ease with which one could fill up gaps by a carefully-performed plastic operation.

CAST OF THE BLADDER.

Dr. H. J. BOLDT presented a cast of the bladder, which was obtained in the case of a woman 18 years of age who had recently been confined with her first child. Labor was normal, but soon afterwards she felt pain in the hypogastric and lumbar regions, and examination showed albumen, blood, and a small quantity of pus in the urine. The temperature was 102.6°. The diagnosis of catarrhal nephritis was made. One day while urinating the patient felt an obstruction in the urethra, and on making examination subsequently Dr. Boldt felt a membrane at the urethra which he believed to be partial inversion of the bladder, and replaced the presenting part. It again protruded on several occasions, and Dr. Lusk saw the patient in consultation, and likewise expressed the opinion that there was a tendency to inversion of the bladder. The presenting sac became somewhat putrid, and was sprinkled with iodoform. It was finally discharged, and Dr. Boldt expressed the opinion that it was composed of mucous membrane, submucous tissue, and perhaps some of the muscular fibres of the vesical wall. There seemed to be complete denudation of the bladder, and its walls afterwards became thickened, and contracted upon the cavity. The temperature rose, and soon after the expulsion of the membrane the patient died with cerebral symptoms, thought to be of septic origin. An autopsy could not be obtained. Death took place about twenty

days after confinement. Dr. Boldt said such cases were extremely rare; but few had been recorded in Europe, and he believed none in this country. The patients invariably died.

Dr. CARPENTER thought a case of cast of the bladder had been reported to this Society, and also to the New York Obstetrical Society.

Dr. PRUDDEN expressed doubt as to whether the specimen was the mucous membrane of the bladder and not a new formation.

LARGE SARCOMA OF THE OVARY.

Dr. CUSHIER presented a very large sarcomatous tumor removed from the abdominal cavity, attached to the uterus, but probably having its origin in the left ovary. It had grown rapidly, and had greatly reduced the patient's strength. Dr. Hunter saw the patient in consultation, and an exploratory incision was made; but the nature of the growth and its adhesions deterred them from removing it. The patient died five days later of exhaustion and disappointment in not having the growth removed. The retroperitoneal glands were enlarged, and there were some nodules in the lungs. The great rarity of sarcoma originating in the uterus, pointed out by Leopold, led her to believe this one began in the ovary, although the microscopical examination failed to decide this question conclusively. The growth was composed of round and spindle cells.

DERMOID CYST OF THE OVARY.

Dr. CUSHIER also presented a dermoid cyst of the ovary removed on Thursday last. The tumor had grown rather rapidly. Its attachments were numerous, but not firm, and it was removed without difficulty. The hair was limited to a small pouch in the larger sac, the greater cavity containing chiefly sebaceous matter.

DEATH FROM CONGENITAL CYANOSIS.

Dr. L. E. HOLT presented the heart, lungs, and kidneys removed from the body of a child which died forty-eight hours after birth. It weighed between four and four and a half pounds, was cyanotic at birth, breathed very rapidly, the pulse could not be counted. It died quietly. The lungs sank in water, were firm; it was scarcely possible to find any distended air-cells with the unaided eye. The foramen ovale was sufficiently large to admit the tips of two fingers; the valves were not abnormal. The spleen was twice its normal size, hard, and congested. The kidneys showed interstitial inflammation and uric acid infarctions. There was a decidedly syphilitic history, and it was a question whether this disease may not have been connected with the abnormalities mentioned.

The Society adjourned.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held October 15, 1885, A. JACOBI, M.D., President, in the chair.

THE COMPARATIVE RESULTS OF SURGICAL OPERATIONS IN BELLEVUE HOSPITAL.

STEPHEN SMITH, M.D., the author of the paper, thought there was no better place in which to test the progress of practical and operative surgery than in the wards of Bellevue Hospital. This institution had within its walls and environments all the conditions which would now be regarded as unsanitary. Although many changes had been made within the interior, the serious defects of locality and construction still remain unaltered. During nearly the entire thirty-five years during which Bellevue had been a surgical hospital Dr. Smith had been personally familiar with the practice in the several surgical divisions. The practice of surgery had within the period mentioned undergone so complete a revolution that one of the older surgeons would scarcely realize that he was in the same hospital where he had practised a few decades ago. At that time, before the introduction of anæsthetics, the chief principle which actuated him in his operations was celerity; but now, while the surgeon desires to render the period of anæsthesia as short as practicable, mere celerity was mentioned only to be condemned.

The author then contrasted the several details of former surgical procedure with the practice of to-day. Before the use of antiseptics, little thought was given to securing cleanliness. The surgeon placed his cutting-instrument (when not in use) wherever it was most convenient; the ligatures were carried in his pocket; the accumulated secretions of the skin and other filth were allowed to remain on the limb even during major operations. In his personal preparations the surgeon sought only to avoid soiling his clothes; the bystander was asked to examine wounds with unwashed hands; the sponges were carriers of filth, and were only washed in simple water; one end of the ligature only was removed, the other being left to make traction upon when final separation from the vessel should take place; suppuration was expected, and the wound was left open at the most dependent portion to allow of the escape of pus; adhesive plaster was applied which had not been rendered aseptic, and the stump was wrapped in unbleached muslin which had not been specially cleansed.

The methods in use at the present time were then placed in contrast with those of the past. The surgeon formerly prepared the wound for suppuration, while he now dressed it for union without suppuration. Both uniformly realized their expectation. As a result of former methods, the surgeon

had pus, fever, septicæmia, perhaps pyæmia, exhaustion of the patient; and in major operations, as larger amputations, etc., death often ensued.

The dictum of Hunter, that compound fractures commonly suppurate, was formerly the guiding principle, but to-day compound fractures were welcomed to the wards of the hospital as a class of cases which gave most satisfactory results. Amputation was not thought of except where arteries and nerves were so destroyed as to prevent nutrition. The treatment now pursued in compound fractures is designed, first, to remove from the wound every particle of matter liable to injure the tissues and induce suppuration; second, to place in fixed apposition the various tissues involved in the wound; third, to cleanse and disinfect the wound and protect it from becoming soiled during recovery; fourth, to protect the wound from any movement of the parts entering into it while the process of repair is going on.

Formerly, the excision of large joints was a most dangerous operation; but now these wounds, as a rule, healed by rapid and healthy granulation. Perhaps the most marked illustration of the great improvement in operative surgery in Bellevue Hospital might be found in the unvarying success which now attended the treatment of simple fracture of the patella by wiring together the fragments.

Septicæmia and pyæmia are now seldom seen in the pavilions devoted to gynæcology. Since November, 1883, Dr. Wylie had performed laparotomy thirty times, with five deaths. Of the cases proving fatal, two were hysterectomies, one for cancer of the uterus, and the other two for myomata weighing fifty pounds.

Cleanliness was the one great object sought to be obtained in all operations. The conditions regarded as essential to success might be summarized as follows: a clean operator, clean assistants, a clean patient, clean instruments, clean dressings.

Dr. A. C. Post was prepared to accept the statements of the author regarding the efficiency of thorough cleanliness of wounds. He thought, however, that there is still some doubt as to how far antiseptics, so called, contributed to the success of operations. But thorough cleanliness is, without doubt, a very important matter in the treatment, and seclusion of the wound from external malign influences is also a very important item. His reason for doubting somewhat the part played by antiseptics in the treatment of wounds was founded upon the experience of the most eminent gynæcologists of Great Britain, Mr. Tait and Mr. Keith, who regarded antiseptics as not only useless, but as pernicious,—claiming, indeed, that they add slightly to the mortality. But, at the same time, they both insist very strongly upon entire cleanliness. There can be no doubt as to the great improvement which has taken place in the treatment of surgical wounds, whether that improvement is to be referred to the antiseptic methods directly or to cleanliness.

Dr. W. G. Wylie did not know whether we should have ever known the full value of cleanliness had it not been for the introduction of antiseptics. Antiseptics had done a great deal of good; but, like all other good things, they had been carried too far, and there was now somewhat of a reaction against them. If the methods of Tait and Keith are studied, it will be seen that if they do not use antiseptics it is because they secure such complete cleanliness that antiseptics are not necessary. If he could feel perfectly satisfied that he could always secure entire cleanliness, he might give up the use of antiseptics.

Dr. F. V. White asked Dr. Smith what had been his results from the use of the wire in fracture of the patella; whether or not he had gained bony union.

Dr. W. M. Carpenter had been for many years an observer of the treatment of surgical wounds in the Bellevue Hospital, and had been able to trace the results in the fatal cases as they appeared at autopsy. Formerly, before the adoption of antiseptics and cleanliness, surgical kidney, etc., was not of infrequent occurrence; but it had now become a thing of the past. The so-called surgical kidney was no more to be seen in the dead-house.

Dr. Smith, in closing the discussion, said he had not intended to dwell specially on the subject of antiseptics, but he might say that his own opinion was that extreme cleanliness had secured the present excellent results in surgical practice in Bellevue Hospital. Antiseptics, he thought, have simply brought us to a knowledge of the necessity of cleanliness; they are adjuvants to cleanliness. But those surgeons who ridicule antiseptic methods are doing harm, for not every one who follows their advice in discontinuing the use of antiseptics would be able to secure the degree of cleanliness which they obtained by other means. Besides, they do make use of carbolic acid, etc., in cleansing sponges and preparing for the operation.

In answer to Dr. White's question, he said that he had wired the fractured patella seven times, and had obtained what appeared to be bony union; but whether it was so or not he could not positively say.

The Pathological Society of Philadelphia, at its semi-annual meeting held on the 22d instant, was addressed by Dr. J. Collins Warren, of Boston, whose theme was "A Comparison of the Changes in Arteries after Ligature and in the Ductus Arteriosus after Birth." Later in the evening a reception was tendered to Dr. Warren at the St. George Hotel. A lunch was also given to Dr. Warren by Dr. J. C. Wilson.

NEW BOOKS.

A Practical Treatise on the Diseases of Children. By Alfred Vogel, M.D. Translated and edited by N. Raphael, M.D. Third American from the Eighth German Edition, Revised and Enlarged. Illustrated by Six Lithographic Plates. New York, D. Appleton & Co. 1885. Pp. 637.

The Science and Art of Midwifery. By William Thompson Lusk, A M., M.D., etc. New Edition, Revised and Enlarged. With numerous Illustrations. New York, D. Appleton & Co. 1885. Cloth, 8vo. Pp. 763.

Alpine Winter in its Medical Aspects. With Notes on Davos Platz, Wiesen, St. Moritz, and the Maloja. By A. Tucker Wise, M.D., etc. Second Edition. London, J. & A. Churchill. 1885. Pp. 121.

The Physician Himself, and what He should Add to his Scientific Acquirements in Order to Secure Success. By D. W. Cathell, M.D. Fifth Edition, Thoroughly Revised. Baltimore, Cushings & Bailey. 1885. Pp. 284.

Practical Surgery: Including Surgical Dressings, Bandaging, Fractures, Dislocations, Ligature of Arteries, Amputations, and Excisions of Bones and Joints. By J. Ewing Mears, M.D., etc. With Four Hundred and Ninety Illustrations. Philadelphia, P. Blakiston, Son & Co. 1885. Cloth, 12mo. Pp. 794.

A Doctor's Experiences in Three Continents. By Edward Warren, M.D., C.M., LL.D., Bey by Khedival Firman, etc. In a Series of Letters addressed to John Morris, M.D., of Baltimore, Maryland. Baltimore, Cushings & Bailey. 1885. Pp. 613.

Applied Medical Chemistry. A Manual for Students and Practitioners of Medicine. By Laurence Wolff, M.D., etc. Philadelphia, P. Blakiston, Son & Co. 1885. Cloth, 8vo. Pp. 174.

Milk-Analysis and Infant-Feeding. A Practical Treatise on the Examination of Human and Cow's Milk, Cream, Condensed Milk, etc.; and Directions as to the Diet of Young Infants. By Arthur V. Meigs, M.D. Philadelphia, P. Blakiston, Son & Co. 1885. Cloth, 12mo. Pp. 102.

Post-Mortem Examinations, with Especial Reference to Medico-Legal Practice. By Professor Rudolph Virchow, of the Berlin Charité Hospital. Translated by F. P. Smith, M.D., etc. With Additional Notes and New Plates. From the Fourth German Edition. Philadelphia, P. Blakiston, Son & Co. 1885. Cloth, 12mo. Pp. 138.

Epitome of Diseases of the Skin. Being an Abstract of a Course of Lectures delivered in the University of Pennsylvania during the Session of 1883 and 1884 by Louis A. Duhring, M.D. Reported by Henry Wile, M.D. Philadelphia, J. B. Lippincott Company. 1886.

NEW REMEDIES AND CLINICAL NOTES.

Carbolic Acid in the Treatment of Malignant Pustule.—A case is reported by Dr. Buck of a veterinary surgeon, 31 years of age, who had the characteristic lesion of malignant pustule appearing upon the back of the right wrist exactly twelve days after examining an animal which had died with anthrax. The patient, on the third day after the blister was noticed, had a temperature of 104°; he had rigors and a coated tongue. Pure carbolic acid was injected under the livid spot, large and frequent doses of sodium hyposulphite were ordered, and the patient put on a meat diet. Four days later, carbolic acid was again injected. The patient rapidly recovered, but the eschar did not finally separate for nearly six weeks; the ulcer then soon healed. The result was attributed to the injection of the pure carbolic acid, which did not seem to be painful.—*British Medical Journal.*

Chloride of Calcium.—Dr. R. W. Creighton (in *The Practitioner* for September) says a good word for a remedy that has experienced great vicissitudes of fortune. In scrofulous manifestations, with or without attendant suppuration, this salt of lime he found to produce admirable results. The effects of lime salts upon the heart, in increasing its force, have been established by Sydney Ringer's experiments, and were observed clinically by Dr. Creighton. The crystallized chloride of calcium is given in doses of one, two, or three grains for young children, and rarely more than twelve or fifteen for adults. Coghill's formula of five ounces of the crystallized salt in twelve fluidounces of syrup is the preferred form of administration, in doses of five to sixty minims, according to age. It is usually given in milk after meals.

Quinine for Hypodermic Injections.—Dr. L. Aitken advocates the hypodermic administration of quinine in acute intermittent fever, preferring the hydrochlorate and bisulphate, the latter being the cheaper. A mixture is made of pure glycerin and distilled water, of which six minims at the temperature of the body would readily dissolve one grain of the salt. To this two per cent. of carbolic acid is added. Thirty minims of this solution, containing five grains of the bisulphate, may be injected into the subcutaneous cellular tissue, and repeated if deemed necessary.—*British Medical Journal,* October 10.

Nitrite of Sodium in Gout-Epilepsy.—

℞ Sodii nitritis, gr. xxxvj;
Sodii hippuratis, ʒiij;
Inf. serpentariæ, q. s. ad fʒxij. M.

One ounce to be taken before meals, three times a day. The sodium nitrite should be carefully increased until it reaches fifteen grains, although some cases yield to ten grains. In case there is constipation and jaundice the following may be used:

℞ Iridin, gr. ij;
Ext. cascaræ sag., gr. iij. M.
Ft. pil.

To be taken at night, and repeated each night until the symptoms are overcome.—J. M. Granville, *Brit. Med. Journ.*, p. 700.

Nitrite of Amyl in Gout.—One of the effects of inhalations of nitrite of amyl in health is to increase the quantity of urine and its contained uric acid. Dr. A. D. Macdonald, of Liverpool, having tried to utilize this property in the treatment of a paroxysm of

gout, found that it had the same effect upon the excretion of uric acid, and gave speedy relief. It was given in the usual doses (℥iv to v) by inhalation, repeated several times, at intervals of two hours. It is suggested that it may be also employed as a prophylactic when an attack is threatened.

MISCELLANY.

A Post-Mortem in Public.—A valued correspondent sends a clipping from the *Providence Journal* of October 18, 1885, concerning a post-mortem held in a public cemetery in Newport the day before:

"The remains were taken from the coffin and placed upon the lid of the outside box, which was used as a dissecting-board. A search was first made for the ball which was fired into the breast. The ball penetrated the skin three inches inside of the left nipple, going through the left ventricle, passing the eighth and ninth ribs about three inches from the spine, where it was lost. The heart and liver were removed from the body, and the greater part of the intestines also, by which action the physicians were enabled to reach the conclusion as to what effect his shot would have. For over an hour a search was made for the ball, but after a large quantity of the flesh had by a process of chopping been reduced as small as mince-meat the effort to discover its whereabouts was given up, and attention was given to the wound in the head. The hole in the scalp is some two inches from the top of the right ear. The scalp was thrown back and sawing was commenced. The brain was very large indeed. Considerable dissecting had to be performed, and finally the bullet was found in the posterior portion of the cerebrum of the left side. Almost immediately Dr. —— exclaimed, 'That proves that it did not wound the cerebellum.' The finding of the ball in the head was a matter of much satisfaction, of course. The remains were then put together in the coffin and reinterred."

He adds some vigorous comments, which express the sentiment of a number of the medical profession upon this extraordinary occurrence:

"The cemetery is very accessible, and it is exceedingly fortunate that comparatively few knew of the intended operation. The poor man was supposed to have committed suicide, but, some doubt having arisen, and ugly rumors having gained some circulation, the post-mortem was ordered, with all the disgusting details already quoted. In the first place, the subject was a colored man; but certainly his poor family were entitled to as much consideration as any white people. It is no legitimate excuse to urge that he was simply a nigger! What interests the community most is the fact that under the same officers such scenes can be and perhaps may be repeated.

"To remove a body from its grave and coffin, and use the outside coffin for a dissecting-table, and then calmly, in the sight of the populace, to 'chop the body into mince-meat,' is a spectacle so disgusting and an operation so beneath the dignity of professional gentlemen that words fail sufficiently to condemn the act!

"In a large experience, I have never known of such an outrage upon both dead and living, and such a prostitution of professional power. Those concerned in it have certainly disgraced themselves by being present, and the sooner they realize this fact the better for all concerned.

"Unquestionably we need a dead-house or morgue, but until one is provided let the dead be respected by decent treatment under suitable shelter, and in some retired place away from the eyes of those who have no right to see.

"Such proceedings debase the witnesses, and as illustrations of barbarism rank with the deeds of vigilance committees or the public hangings of frontier towns."

Oleomargarine and Butter Substitutes.—The recent suits in the courts against the stringent laws prohibiting making or selling oleomargarine have been generally successful in establishing the proposition that the manufacture of imitation butter is not in itself wrongful and cannot be absolutely prohibited. This at least is the purport of the recent decision in the New York Court of Appeals. In this State (Pennsylvania) a test-suit is pending, with every probability of a corresponding result being obtained. It appears, therefore, that the only province of the legislative bodies is to enact as stringent laws as they deem proper to prevent the manufacture or sale of oleomargarine under the guise of genuine butter.

There is now another decision in a New York court of considerable interest on the general subject of adulteration.

The statute says that milk to be salable must not contain more than eighty-eight per cent. of water or liquids, and a violation of this provision was the subject of a recent prosecution. In defence the milkman claimed that, while the milk was not of the proper standard, it was just as it came from the cow, and offered to prove this statement. He was not allowed to do so, and a conviction resulted. An appeal having been taken from this verdict, the conviction was reversed, on the ground that the Constitution forbade the Legislature from taking away private property without just compensation, and this would be the practical result of the conviction.

The case was reopened, and the milkman will have an opportunity of proving his statement if he can.

Anti-Vaccination Excitement in England.—The furor against vaccination in some

parts of England is hardly intelligible in this country, where the opposition has been comparatively slight. The agitation is ostensibly directed towards compulsory vaccination, which the law gives the health-officers power to require, but practically shows an entire disbelief in the efficacy of vaccination in any case. This is shown by the fact that Dr. Jenner was recently hung in effigy in one of the large towns in central England, while a horse and cow were exhibited in wagons to bring ridicule upon the source of the great physician's remedy. A coffin on an open bier symbolized the results of the discovery. The fact that occasionally serious harm has resulted from impure vaccine matter has been taken advantage of by the opponents of the system, and it has had great effect upon the ignorant masses.

The vast accumulation of statistics showing the beneficent results of vaccination have been published again and again, but without having much apparent influence upon the agitation.

Responsibility for Damage done by Sewage.—A recent English decision enforces the health-laws by requiring a person to take proper care of the sewage from his house. It appeared that it percolated through the ground and entered the well of a neighbor, rendering it unfit for use. Under these circumstances, it was held that the plaintiff was entitled to an injunction forbidding the discharge of the offensive matter in the way it had been.

Death of Prof. McSherry, of Baltimore.—A special meeting of the Medical and Chirurgical Faculty of Maryland was held October 10, to take action upon the death of the late Prof. Richard McSherry, M.D., whose loss is universally felt in the city where he had practised medicine since 1851. At the time of his death he was Professor of Theory and Practice of Medicine in the University of Maryland, and President of the State Board of Health.

Dr. Benjamin Lee has removed his offices and Hall for Remedial Exercise and Massage to No. 313 South Fifteenth Street. He continues to reside on Manheim Street, opposite McKean Avenue, Germantown.

The Ninth Annual Meeting of the American Academy of Medicine was held at the New York Academy of Medicine, 12 West Thirty-first Street, New York, on Wednesday and Thursday, October 28 and 29, 1885. A report of the proceedings will appear in our next issue.

"Colden's Liquid Beef Tonic," according to Dr. Benjamin H. Briggs, Selma, Alabama, is an excellent preparation of known composition, and it is one that physicians can intelligently prescribe. He has found it of great service in his practice.

Dr. A. Van Harlingen has removed his office to No. 118 South Seventeenth Street.

Dr. T. H. Bradford has removed to No. 125 South Eighteenth Street.

Dr. W. H. Parrish has removed to 1435 Spruce Street.

NOTES AND QUERIES.

A CORRECTION.

Dr. Stanley Sutton writes that in the report of the discussion of the proceedings of the American Gynæcological Association he did not make the remark credited to him on page 26, and that, in fact, his sentiments are really in accord with those of Dr. Chadwick, and not opposed, as was stated. Our apologies are due to Dr. Sutton for the mistake; and we regret that our report credited him with a remark made by another.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 11, 1885, *TO OCTOBER* 24, 1885.

Colonel T. A. McParlin, Surgeon.—Directed to await further orders in New York City. Letter from A. G. O., October 19, 1885.

Lieutenant-Colonel E. P. Vollum, Surgeon.—Assigned to duty as Attending Surgeon, Headquarters Department of the Platte, Omaha, Nebraska, relieving Assistant-Surgeon William C. Shannon. S.O. 103, Department of the Platte, October 15, 1885.

Lieutenant-Colonel B. J. D. Irwin, Assistant Medical Purveyor.—Ordered from Department of Arizona to New York City, for temporary duty in charge of Medical Purveying Department at that place, relieving Captain Henry Johnson, Medical Storekeeper. S. O. 233, A. G. O., October 10, 1885.

Major Anthony Heger, Surgeon.—Directed, in addition to his present duties as member of Army Medical Examining Board now in session in New York City, to perform the duties of Attending Surgeon in that city. S. O. 240, A. G. O., October 19, 1885.

Major Joseph C. Baily, Surgeon.—Granted leave of absence for twenty days. S. O. 225, Department of the East, October 19, 1885.

First-Lieutenant Edward R. Morris, Assistant-Surgeon (recently appointed).—Ordered for duty in Department of Missouri. S. O. 233, A. G. O., October 10, 1885.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM OCTOBER 11, 1885, *TO OCTOBER* 17, 1885.

Passed Assistant-Surgeon J. B. Baldwin.—Detached from Naval Hospital, Philadelphia, and ordered to Navy-Yard, Mare Island.

Surgeon D. Dickinson.—Detached from Naval Hospital, Mare Island, and ordered to Training-Ship "Portsmouth," as relief to Surgeon A. M. Moore.

Surgeon A. M. Moore.—Detached from Training-Ship "Portsmouth," and wait orders.

Assistant-Surgeon Joseph Shafer.—Detached from Receiving-Ship "St. Louis," and ordered to Naval Hospital, Philadelphia, as relief of P. A. Surgeon Baldwin.

Assistant-Surgeon F. A. Hester.—Detached from U.S.S. "Minnesota," and ordered to the "Tennessee," as relief of P. A. Surgeon Nelson H. Drake.

Passed Assistant-Surgeon Nelson H. Drake.—Detached from the "Tennessee" 31st instant, and wait orders.

PHILADELPHIA, NOVEMBER 14, 1885.

ORIGINAL LECTURES.

ON CASES OF SKIN-DISEASE.

Delivered at the New York Hospital

BY L. DUNCAN BULKLEY, M.D.

DIFFUSED PAPULAR SYPHILIDE.

GENTLEMEN,—This is a case of diffuse lenticular papular syphilide, which is now fading away. Last week each one of these papules was encircled by a roseolous spot. Nothing remains now but staining. On making pressure on these spots you will perceive that they are due to pigmentation. If they were vascular, the spots would disappear on pressure; these, as you see, do not. The eruption is confined chiefly to the flexor surfaces and to the trunk. The skin-disease made its appearance after the patient had a chancre; but it would not be likely to be mistaken for any other disease. If it were eczema there would be more inflammatory action, and the disease would exist in patches. Psoriasis would not exist to such an extent on the flexor surfaces without also involving the extensors. I wished to show you the pigmentary syphilide, and also the diffused macules around each papule.

SYPHILIS PALMARIS.

I showed you this case of palmar syphilis with eczema at my last lecture. I then called your attention to the chief diagnostic points in connection with the disease,—viz., that the eruption was mainly made up of papules arranged in double rings, with a wavy outline and well-defined margin. He has been under the mixed treatment of bichloride of mercury and iodide of potassium, and locally the glycerole of the subacetate of lead and glycerin, each twenty grammes in one hundred and twenty-eight grammes of water.

GENERAL SYPHILIS, WITH PALMAR LESION.

In speaking of the case of palmar syphilis just shown, I told you two weeks ago that the early syphilides when appearing on the hands generally affected both sides symmetrically. This case I now show you is only of early syphilis: it is about two years since the chancre was first noticed. You will notice that the eruption is made up of separate isolated papules, but which have a tendency to exist in groups of a circular outline. They are erythematous and hard, but there is no thickening, and not much scaling. A papular syphilide also exists on the knees and legs. We sometimes see an erythema resembling this eruption somewhat, but the arrangement is not similar. In ninety-nine out of every hundred cases of skin-disease of the palm we may suspect syphilis. The patient is at present under the mixed treatment.

PSORIASIS PALMARIS.

Two weeks ago I showed you an eruption existing on the hand, in which it was somewhat difficult to make a diagnosis between eczema and syphilis. To-day I show you this case of general psoriasis together with palmar psoriasis, which I said when speaking of syphilis of the palm, at the last lecture, was a rare lesion. The patient is 37 years of age, and he has had psoriasis nine years. It is generally diffused over the body; the flexor surfaces are, however, spared even where there is a great amount of the disease in the neighborhood. On the back and arms the eruption is guttate and nummular; in the latter situation it is also confluent. The skin of the penis and the glans penis are also affected. On examining the hands we find separate scattered spots, with no tendency to run together, spreading peripherally, and healing in the centre; no fissures are to be found, and on removing the scales from a papule, a reddened bleeding surface is exposed. The head, neck, and face are also covered with a similar eruption. The tongue does not present any scales, even with so large an amount of eruption elsewhere. I do not believe in the existence of a psoriasis linguæ, and consider the white patches which are sometimes seen on the tongue nothing more than a degeneration of the epithelium, being some form of commencing epithelioma.

PSORIASIS DIFFUSA.

D. K., a German, 55 years of age, has had the present eruption over ten years, which commenced on the head, affecting the knees, back, and lately the elbows. He is the father of four children, three of whom are healthy, the other has hip-disease. The patient had a chancre when he was young, but it was not followed by an eruption. He also had acute rheuma-

tism, but with these exceptions has always enjoyed good health. When the patient presented himself to me he showed me an eruption existing to a slight extent on the elbows, and to one not familiar with the disease it would be difficult to make a diagnosis from so small an amount of disease. On examining him carefully I found small, scattered scaly spots existing on the extensor surfaces of both arms. They were of a pearly-white color, and when removed the limiting membrane was shown, and beneath the reddened and bleeding corium. On the back is seen a more or less circular eruption, existing in scattered spots. The thighs are also affected, but to a limited extent. On examining the scalp an eruption is found, but, on account of the frequent washing, nothing characteristic can be seen.

This case shows the necessity of examining carefully all parts of the body before making a diagnosis, because if you do not you will often make mistakes as to the nature of the disease.

EPIDERMIC FAVUS.

The next case is one of epidermic favus. The patient is 10 years old, and gives no history of contagion. The eruption consists, as you see, of a patch of diseased skin, nearly circular, and about two inches in diameter, situated over the left malar bone and extending down on the cheek. It is circular like ringworm, and yellow masses are seen which, when removed, leave cup-like depressions. At first glance one not accustomed to see skin-diseases would not suppose it was favus, but would think it was either ringworm or erythematous eczema. In tinea circinata there would not be these cup-like masses and yellowish, sulphur-like color, nor the peculiar odor, and if it were a case of eczema there would be a history of moisture. The commonest mode of contagion is from cats: the cats get it from mice; and it is transmitted to human beings by the cats, although it occurs less frequently in cats than in mice.

FAVUS OF THE SCALP.

In this girl there is the same eruption, occupying a vast surface, with cups around the hair, with a peculiar odor. These distinct masses are not inflammatory, but are simply dry sulphur-like crusts which readily crumble into a fine powder, in which the spores of the *Achorion Schönleinii* are found. It is very contagious. The cups are the diagnostic mark; but, if we do not find these cups, upon examining the crusts we shall find the parasite (Achorion Schönleinii). The patient is 12 years of age, and has had the disease since she was cutting her eye-teeth, or when she was about five years of age. It commenced in a small spot about the size of a quarter of a dollar. There is no traceable history of contagion. Where we remove the crusts a red surface is exposed, which remains so for some time. The surface is red and shining, it does not exude, and the disease has eaten down to the rete Malpighii, which is laid bare; it does more than that, it eats down wherever it finds dermal tissue. The patches are generally oval in shape, mostly of a greenish color; the hair is thin. It destroys the hair more than tinea. There are spots where the hair will not grow; that is, where we see the head red and shining. If we arrest the spread of the disease now, there will be sufficient hair left to grow and cover the whole of the head. There will be some bald spots, but not enough to show. As the disease spreads, it passes down the hair-follicle and root-sheaths, destroying the hair-follicle. I show you some of the Sydenham Society's plates which are marked herpes tonsurans, but are really favus. I show you a model showing the disease as it appears on the upper lips: the scales have been removed, and nothing remains but the cups.

We have here two cases which present the forms in which favus may appear. With regard to the prognosis in the boy, it is by far the best, as all we have to do is to pick out the crusts and rub in a little diluted citrine ointment: it will be well in a week. I have picked out one of the crusts from the boy's cheek: it is the prettiest demonstration I have ever made or seen,—the yellow solid mass circular, with its upper part cupped and depressed. The child with the favus capitis may be a year in being cured. If in a hospital, it might be cured in a month. It is difficult to be exact as to the time of effecting a cure, as individual cases vary much. The treatment is local, and consists in epilation, as the fungus reaches down to the bottom of the hair-follicle and it has to be removed. The hair should be cut short before commencing treatment, and after epilating a five-grain solution of the bichloride of mercury should be rubbed into the diseased patches with your own hands.

ACUTE PUSTULAR ECZEMA.

This case of acute pustular eczema over the face and scalp I have shown you several times before. The skin is dry and harsh; there is congestion and thickening of the skin of the face, also thickening and scaling of the scalp. I show you the case that you may see the good effects of treatment, and also the rebellious nature of the disease. The child is still using linseed oil and oil of cade. As there is not much itching, and as constant stimulation may increase the thickening, we will omit the oil of cade and continue the alkaline baths, and afterwards anoint with linseed oil. At first she took acetate of potassium, with spiritus Mindereri to stimulate the activity of the skin, and also cod-liver oil. She is now taking a tonic containing arsenic, iron, etc.; but I think that she will do better under an alkaline treatment.

ERYTHEMATOUS ECZEMA.

As we learn a great deal from seeing diseases in the various stages of treatment, I show you this girl with erythematous eczema of the head and forehead. When we first saw her, you will remember, the eruption was moist; now it is dry. I do not allow patients with eczema to wash as often as they desire, but tell them when to do so. She has been taking: ℞ Sol. Fowleri, f℥ij; Mist. rhei et sodæ, f℥iv; a teaspoonful three times a day after meals. Locally: ℞ Ol. cadini, ℥i, Ungt. zinci oxid., Ungt. simplicis, āā f℥ss.—M. Two weeks ago she was using ungt. zinci oxidi et plumbi.

I do not know whether you have all felt and appreciated the swelling of the glands in the neck. They were at one time enlarged to a great extent, as a result of inflammation. Some would think that it was due to syphilis; but it is not.

ECZEMA RUBRUM OF THE LEG TREATED WITH RUBBER BANDAGE.

This colored man has had the eruption which you see on his leg since February, 1879. It made its appearance at the junction of the middle and lower thirds of the leg, as the result of a burn, which he painted with iodine. This, causing irritation, gave rise to an eczema, which spread until it now occupies the entire left leg, extending up on to the thigh, and being limited below as if it were marked out by the band of his slipper. On the right leg there are marks of eczematous sores. He says that these latter were never ulcers, and that it is not more than a month since they healed up. He gives no history of any previous eruption.

I had him keep the bandage on the leg that you might see its operation in eczema. It produces a great deal of sweating in ulcers; in eczema it causes a dryness and scaling, much of the function of the sweat-glands being arrested. The beauty of the rubber bandage is that it does not denude the surface, and that it possesses the advantage over the ordinary bandage of permitting the patient to walk and stand on it, yielding with the leg and foot. The leg has now ceased to exude; but if you allow the bandage to remain off for a length of time it will exude again. I have seen the diseased surface cease to exude altogether and have healthy tissue underneath. The bandage should be taken off at night, washed, and hung up, and the leg also washed.

ECZEMA CAUSED BY FLANNEL.

I show you this case merely for diagnostic purposes. You here see the results of scratching, the irritation being undoubtedly due to the use of red flannel. Some may say that it is not an eczema, but a dermatitis; but, from its extreme itchiness, thickening, and chronicity, I would call it an eczema.

ORIGINAL COMMUNICATIONS.

MYALGIA.

BY JAMES C. WILSON, M.D.,

Physician to the Philadelphia Hospital and to the Hospital of the Jefferson Medical College, etc.

A VERY large proportion—much larger than is commonly supposed—of cases in which pain is the principal symptom are due to myalgia. This affection may be defined as a morbid condition of voluntary muscles, of which the chief and often the only symptom is pain on movement. Myalgia, as a general term, has few synonymes: it is sometimes called myodynia. This affection has no essential relation to rheumatism or the rheumatic diathesis. Therefore the common use of the term "muscular rheumatism" as a synonyme for myalgia is an error. This error has occasioned much confusion of thought and mistaken medication, and tends to main-

tain the obscurity which overhangs the subject of the so-called (and often miscalled) rheumatic affections in general. That true rheumatic processes may extend from serous or fibrous structures to contiguous muscular masses has (in the absence of demonstration) been assumed by many writers of authority; but that acute or subacute rheumatism, with its recognized characters, ever manifests itself primarily or exclusively as an inflammation of muscle-substance is an assumption wholly without clinical or pathological support. The term myo-rheumatism is as inapplicable as muscular rheumatism, and lacks the sanction of usage. Myositis is a term used to describe (1) an acute inflammation of muscle often traumatic and commonly attended by suppuration; and (2) a chronic, indurating, inflammatory process, not infrequently due to syphilis. Neither of these conditions resembles the affection under consideration in its clinical aspects, nor is allied to it pathologically.

As manifested in particular muscles or groups of muscles, myalgia has long been described under the terms cephalodynia, torticollis (*m. cervicalis*), pleurodynia (*m. pectoralis vel intercostalis*), lumbago (*m. lumbalis*), dorsodynia, omodynia, scapulodynia (*m. dorsalis*), etc.

This affection must, in the present state of our knowledge, be classified with the diseases of nutrition in the more narrow sense. It is not a diathetic disease.

To Dr. Inman, of Liverpool, is due the credit of first having pointed out the frequency of this malady and the ease with which it is mistaken for other and much more serious diseases,—an error in diagnosis which has been followed by grave results, especially in the case of nervous and self-centred females and other hypochondriacal persons. It cannot, however, be denied that this author, carried away by his enthusiasm, exaggerated the importance of this local affection at the expense of undervaluing the frequency and significance of other painful disorders which have their origin in the nervous system.

To Dr. Inman we also owe the term myalgia, which has the positive merit of embodying the idea of pain as the chief symptom of the disorder and the muscles as its seat, and the not inferior negative merit of implying no erroneous theory as to its nature and cause.

This affection is described in few, even among the most recent, text-books. In others it receives merely incidental mention. In the majority of them it is passed over in silence. Yet it is obvious that the descriptions of muscular rheumatism—which are rarely omitted—are based upon and refer to cases of various kinds which for the most part are not rheumatic at all, and very frequently are examples of myalgia.

Myalgia is essentially "pain produced in a muscle which is obliged to work when its structure is imperfectly nourished or impaired by disease." Hence all influences which unfavorably affect the nutrition of the muscles, all diseases which directly affect the integrity of their structure, predispose them to this affection. The defect in nutrition may be only relative to the amount of work the muscle is called upon to do, or there may be absolute mal-nutrition implicating the whole body. The muscle may be impaired by local diseases which affect it alone, or it may share in morbid processes which also involve other and distant structures.

Sedentary occupations, leading, as they do, to poor nutrition of the muscular system from want of proper use and exercise, mal-nutrition from a diet deficient in amount and defective in kind, or in childhood from too rapid growth, the chronic wasting diseases, the state of convalescence from acute maladies, and, finally, degenerative diseases of the muscles themselves, all favor the development of myalgia. Among the acute diseases which by their derangement of nutritive processes especially render those who have suffered from them liable to this painful affection of the muscles during convalescence, is acute articular rheumatism. It is this fact, taken together with the use of a misnomer, that has given rise to the view that the muscles share with the serous and fibrous structures in the lesions of that disease, and that myalgia is "rheumatism" of the muscles.

There is, however, over and above these defects in nutrition an especial predisposition or idiosyncrasy, the nature of which is unknown, which renders certain individuals far more liable to suffer myalgic pain than others. This predisposition is encountered in those who have an inherited or acquired gouty taint, and in those who are free from gout, with perhaps equal

frequency. It is not associated with a special liability to true rheumatism.

The most common exciting cause is overwork pure and simple, especially overwork which brings into excessive and prolonged exercise unaccustomed muscles. Next in frequency is exposure to cold, and especially to damp cold, when overheated or over-fatigued. Finally, inevitable and incessant contractions, such as are physiological and are performed without consciousness or sensation in a healthy state of the muscles, will, in muscles that are defectively nourished or have undergone fatty, granular, or fibroid degeneration, cause more or less distinct myalgia. As examples of myalgia due to the first of this group of causes, I may cite the pain in the adductors of the thighs after a hard ride when out of practice, the epigastric pain in children suffering from measles or other acute affections attended with persistent cough, and the pain of spasm, in particular that which follows tonic spasm, such as occurs from reflex causes in the calves of the legs at night and in bathers. Many of the pains of childhood which are classed in common parlance together under the head of "growing pains" are myalgic in their nature. Examples of the second form may be instanced in the pains of wry-neck or lumbago, such as often occur in those who, being very tired but otherwise healthy, fall asleep in a draught of air, or in those who, coming home at evening in cold weather, find a leaking pipe in the cellar, and, stooping over it to stop it, or in some other emergency of every-day life, bring into excessive use unaccustomed muscles in an atmosphere that is at once cold and damp. Examples of the third group are common enough in the flying or fixed muscular pain and soreness that occur in wasting chronic diseases and in the convalescence of acute maladies where prolonged muscular effort is too early undertaken. Certain forms of præcordial pain met with in degenerative lesions of the muscular substance of the heart are without doubt myalgic in character, and will, when the clinical data of such conditions come to be more fully understood, be recognized as having more or less diagnostic value.

The chief symptom, the one symptom that is common to all cases, is pain. It is sometimes, especially in the acute cases, constant; more frequently it is slight or wholly absent when the patient is at rest, with the affected muscles in full extension. But it is invariably present or aggravated when the muscles are called into action. It is experienced throughout the muscular mass, but is most intense at or near the points of tendinous insertion. Its character is usually stabbing or stitch-like; sometimes it is acutely dragging or tearing, at other times it is like the soreness of a contused or inflamed part. It is—in acute cases frequently, in chronic cases almost invariably — accompanied by a sensation of stiffness in the affected muscles. The pain is essentially the same in all cases, variations in its character and severity being due to differences in the opportunity for physiological rest in different groups of muscles. The most obstinate and severe form of myalgia is that which occurs in the intercostal muscles and their fibrous aponeuroses,—pleurodynia. Here the affected muscles are constantly concerned in the respiratory movements, and have no time for physiological rest except in the intervals of these movements. Scarcely less stubborn and severe are the myalgias of the great muscles of which the principal function is to maintain by their nicely-balanced and ever-varying contractions the erect position of the head and trunk. Less painful and of shorter duration are the myalgias of the limbs: less painful, because prolonged intervals of absolute rest may be voluntarily secured; of shorter duration, because it is by rest that the balance of nutrition is most speedily restored.

Some degree of tenderness usually exists over the whole extent of the myalgic area. It is often, however, slight, except in the region of tendinous insertion, to which it is in many cases wholly restricted. It is not associated with cutaneous hyperæsthesia. Spasm does not, as a rule, occur in the acute cases except when the muscles are brought into use. In chronic cases, however, a condition of tonic spasm, a spastic rigidity, with more or less persistent painfulness, comes on, and in very chronic cases such tissue-changes take place as result in great impairment or absolute loss of contractile power, with or without atrophy.

Objective signs are absent, except that it is evident that the patient assumes by preference an attitude of repose, and that

it keeps the involved structures as much as possible at rest. Pyrexia does not occur. The appetite and digestion are not impaired. Acid sweats are not present. The urine shows no constant or characteristic alteration. There is no tendency to endocardial or pericardial inflammation. If constitutional disturbance be present, it is trifling and due to prolonged local suffering and want of sleep. In by far the greater number of instances the patient remains in his usual health except the local malady.

Myalgia may affect the voluntary, and perhaps also the involuntary, muscles of any part of the body. Those most frequently involved are those subjected to continuous and excessive work and at the same time liable to exposure to cold and damp. The most common and important varieties have already been mentioned.

The aching, dragging pain in the back of the neck, so frequent in poorly-nourished nervous women and in other cases of neurasthenia, the so-called pain of nervous exhaustion, is myalgic. It is felt chiefly during fatigue, is present in the erect posture, and is almost always relieved when the patient lies down. It is referred sometimes to the base of the skull, sometimes to the whole of the back of the neck, but most commonly to the spinal region just above the level of the upper borders of the scapulæ, and constitutes a harassing symptom of the cases in which it occurs. In this connection we must not overlook the fact that many of the pains of that obscure condition to which the term spinal irritation has been applied are myalgic.

The duration of acute myalgia is usually brief, lasting from a few hours to several days; that of the chronic form is indefinite, tending to last years,—sometimes, under unfavorable circumstances, even a lifetime,—with varying periods of exacerbation and remission, which are, after the disease is fully established, much influenced by the phases of the weather.

The essential pathology of myalgia is obscure. The more closely we study our cases, the more obvious becomes the fact that it differs in all important clinical and pathological characters from rheumatism, and that, when these two conditions are associated, the relationship is accidental and not causal. Still less does it resemble neuralgia. It is not an inflammation, as that term is generally understood; but there is ground for the opinion that the lesions are of the nature of a *sub-inflammatory* process within the muscle-substance. The not uncommon instances in which an injury or contusion has been followed shortly after recovery by severe myalgia are of some value as illustrating this theory.

The indications for treatment are threefold: (*a*) relief of pain, (*b*) physiological rest for the affected muscle, (*c*) restoration of the balance between the nutrition of the muscle and the work it has to do.

(*a*) Relief of pain is often secured by rest in a position that permits the complete relaxation of the muscles involved. In acute cases, due to overwork pure and simple, and where complete rest is attainable, little other treatment is required. In the course of a few hours or days the function of the muscles is fully restored and their contractions are performed without pain. When, however, complete muscular relaxation is impracticable or fails to afford relief, anodynes are necessary. Morphia hypodermically is very useful, but this altogether independently of any local action. The continuous application of dry or moist heat by means of hot-water bags, flannels, poultices, spongio-piline, etc., is also useful. Anodyne lotions do good, and liniments containing aconite, belladonna, chloroform, or chloral may be especially recommended, as may also the compound belladonna liniment of the British Pharmacopœia. Plasters of belladonna, conia, and menthol also relieve pain. Galvanism occasionally gives prompt relief. The same statement may be made of static electricity. The pain sometimes disappears under gentle and long-continued massage.

(*b*) Rest is usually enforced, in some degree at least, by the intensity of the pain which attends movement. In severe cases rest in bed becomes a necessity. In affections of the respiratory muscles, as pleurodynia, firm support of the side by means of overlapping strips of plaster drawn from the spine downward and forward in the direction of the ribs to the median line in front is sometimes necessary and always comfortable.

(*c*) The balance of nutrition is restored by rest. Local means to further this end are such as relieve pain,—namely, heat,

anodyne and stimulating frictions, massage, and galvanism. The parts must be protected from sudden changes in temperature by extra thicknesses of flannel or sheets of wool or cotton batting, covered, if necessary, with a piece of oiled silk or fine gum cloth. In old cases, prolonged massage, with passive movements, and the slowly-interrupted galvanic current alternating with rapid faradic currents, are followed by good results.

As constitutional measures, a Dover's powder at night, followed by mild purgation in the morning, is often indicated. Purgation is especially called for in plethoric or gouty persons, in whom also Turkish or vapor baths are of good service; while poorly-nourished, anæmic subjects demand quinine, iron, lime, and cod-liver oil. If the attack linger, full doses of ammonium chloride, and, in old cases, of potassium iodide in moderate doses, well diluted and long continued, are advocated; and in stubborn cases Anstie recommended deep acupuncture of the muscle near its tendinous attachment. In cases marked by a tendency to spastic rigidity, the repeated hypodermic injection of atropine may often be relied upon as the speediest means of cure. Where the general nutrition is poor, the local trouble is apt to be obstinate, and often yields only to measures that restore the general health.

A CASE OF CHOLECYSTOTOMY.*

BY W. W. KEEN, M.D.†

ALBERT HENRY K., German, æt. 45, residing in Philadelphia, was admitted into the hospital September 21, 1885, during the service of Dr. W. W. Keen. Parents healthy. He is the only living one of twelve children; the rest died during infancy.

General health was good, with occasional attacks of gastro-intestinal catarrh. Four years ago he had a severe attack of colic, the pain arising in the right hypochondriac region and extending to the umbilicus. The attack lasted several hours, and was relieved by medicine. The following year he had a similar seizure, followed by a chill, loss of appetite, vomiting, and constipation, and in a short time the conjunctiva was jaundiced.

He had another attack June 12, 1884, followed by nausea, vomiting, chill, loss of appetite, constipation, high-colored urine and clay-colored stools, with marked jaundice of his whole body, which has continued ever since. Since that time the attacks have become more frequent, occurring once or even twice weekly.

Since January 1, 1885, he had been under medical care, but with no improvement. He first came to the dispensary August 6, and was under observation and treatment, but without any change for the better.

Upon admission, it was noted that he had lost some flesh; his mind was dull; the skin, conjunctiva, and mucous membranes were intensely jaundiced; marks of scratching appeared on the abdomen, and he suffered much from itching and stinging at night; the pulse was 54 and full; tongue slightly coated with yellow fur in the morning. His appetite was poor, the bowels costive, and the stools were of a clay color. He also complained of flatulence and constant tenderness and distress in the epigastrium. The urine was high-colored, acid, sp. gr. 1025; no albumen was detected, and no sugar; bile-pigment was present.

Physical examination showed a tumor below the margin of the ribs in the right hypochondriac region; it extended from the right nipple-line three and a half inches towards the median line, and to within two and a quarter inches of the umbilicus. It was not absolutely flat upon percussion, but tender and elastic. The liver-dulness extended from the sixth interspace in the nipple-line to one-fourth inch below margin of ribs. The abdomen was not distended; spleen of normal size; lungs and heart both normal.

September 24. Had severe headache; pain in the epigastrium, followed by a rigor lasting three hours, then fever. 5 P.M. Temp. 101.5°; pulse 80; podophyllin (gr. ½ at night) acted freely on the bowels.

September 28. Dr. Keen introduced into the tumor a hypodermic needle, and thought that he detected a stone. A very small quantity of liquid was withdrawn: it was dark-colored, and mostly blood.

October 1. An aspirator-needle was introduced into the tumor three inches, and a probe passed through it. A stone was detected.

October 4. He had a chill, which lasted three hours, followed by the usual symptoms. The operation which was appointed for the next day was, therefore, postponed.

October 10. Dr. Keen, assisted by Drs. Grove, Mears, O'Hara, Willitts, Elmer, Learned, Boyd, and others, operated, with the usual antiseptic precautions, including the spray, carbolic acid being used.

The surface of the body was first washed off with carbolized water, and etherization was commenced at 1.30 P.M. An incision of three inches was made parallel with the margin of

* Read before the Philadelphia Academy of Surgery, November 2, 1885.

† For the careful notes of this case I am indebted to Dr. Elmer, Surgical Resident of St. Mary's Hospital.

the ribs, commencing one and a half inches below the ensiform cartilage, and extending over the prominence of the tumor. All the vessels were tied with catgut ligatures. The abdominal walls were thick. All hemorrhage had ceased before the peritoneum was opened. Now the liver came into view, and what was thought to be the tumor—the distended gall-bladder—proved to be an enlarged left lobe of the liver, presenting much more to the right than usual. The gall-bladder could neither be seen nor felt.

In order to obtain more room, the incision was prolonged about two inches to the right. The colon and omentum were now exposed. Still the gall-bladder could not be detected with certainty; but a hard mass could be obscurely felt, which was believed to be gall-stones. It lay transversely, directly in front and slightly to the right of the spine, and almost absolutely in contact with it. To obtain still more room to work at such a depth, another incision was made, beginning at the inner end of the first incision, and extending downward in the linea alba three inches. The closest search was made for the gall-bladder, but there was still much doubt as to its situation.

From the posterior part of the transverse fissure, almost in contact with the spine, an apparently uniform mass, continuous with the gastro-hepatic omentum, extended downward and forward, in the posterior part of which, as stated, the gall-stones could be somewhat obscurely felt near the liver; and, farther away from it, a softer mass, which ought to be the flaccid gall-bladder. These lay in such relation to each other that the gall-stones were thought to be in the cystic and the common duct.

Into this softer mass—the supposed gall-bladder—a small opening was made; but it was soon evident that this was the duodenum, as the finger detected the pylorus. Discovering this, the wound in the duodenum was closed with five interrupted and five Lembert's sutures, all of carbolized silk. The harder mass containing the gall-stones was now carefully lifted by the finger and thumb, and the wall and tissues in front of it cautiously incised for about three-fourths of an inch, and two stones, respectively three-fourths and one and one-fourth inches in size, removed. The gall-bladder was as firmly contracted around them as a kid glove clasps the finger, and contained absolutely no fluid. The opening of the cystic duct could be felt by the finger, and was patulous. No other stones could be felt. A probe, it was thought, could be passed from the cystic to the common duct.

The wound in the gall-bladder was stitched with four interrupted and four Lembert's carbolized-silk sutures. All hemorrhage had apparently ceased. The cavity was carefully cleansed, and the abdominal walls, including the peritoneum, were sutured with wire, and the wound dressed with bichloride-of-mercury gauze. The operation lasted until 4.45 P.M. His pulse during the operation was never more than 75 nor under 60, and his skin was fairly warm; but his respiration, from early in the operation, was sighing.

After the operation, he suffered from moderate shock. Hot bottles were applied along his extremities.

5 P.M. Temperature 99.5°; pulse 88. He suffered very much pain, and complained of thirst. Morphine, gr. $\frac{1}{6}$, and cracked ice.

5.30 P.M. Hiccough; relieved by atropia, gr. $\frac{1}{120}$.

7 P.M. Pulse 96, and compressible; temp. $99\frac{4}{5}°$. Morphine, gr. $\frac{1}{6}$. Small quantities of brandy-and-water were given at intervals.

9 P.M. Feeling quieter. Still complains of pain.

11 P.M. Pulse 104; respiration 24. Morphine, gr. $\frac{1}{6}$, was given at intervals. Through the night he gradually failed.

October 11. At 7 A.M., pulse very feeble and rapid; temp. $101\frac{2}{5}°$. Digitalis and brandy were given; but he did not rally, and died at 8 A.M.

The post-mortem examination was made at 12 M. Rigor mortis well marked, though the trunk was still warm. All the abdominal contents were deeply jaundiced. About six to eight ounces of blood were found in the belly, and, as the greater part of it was behind the peritoneum and extended to and around the right kidney, it presumably came from vessels injured in the lifting of the mass in which the gall-stones were situated. This had been carefully done, as it was impossible to obtain access to it otherwise at such depth, but it required some force. No hemorrhage had been observed during or immediately after the operation. There had been no bleeding from the operation-wounds, either in the shrunken gall-bladder, the walls of which were very thin, or from those in the duodenum or the abdominal walls. There was no hemorrhagic tendency noticed, as is so often the case in such operations. There also had been no escape of bile or intestinal contents into the peritoneal cavity. No organs were observed except those concerned in the operation.

The liver, gall-bladder, stomach, duodenum, pancreas, and colon were removed in mass, and the specimens showed the following facts:

The left lobe of the liver, especially its anterior portion, was much enlarged and considerably twisted to the right, so that its semilunar projection occupied the position of the gall-bladder, and was easily mistaken for it before the operation. The liver was deeply fissured between the right as well as the left lobe and the lobus quadratus. No gall-bladder existed in the proper site for it, but it was found lying transversely in a shrunken

condition, as stated, far posteriorly. The common and cystic ducts were patulous, and a probe was passed freely into the gall-bladder from the duodenal end. The wounds in the gall-bladder and the duodenum were effectively closed by the sutures, and no escape of the contents had taken place. No other gall-stones were found. The mucous membrane of the duodenum was deeply congested for a wide extent, undoubtedly from inflammation existing before the operation. The duct of the pancreas was pervious.

So far as I am aware, such complications as this displacement of the gall-bladder, its shrunken condition, and the impossibility of deciding what was and what was not gall-bladder, have not before been reported. It may be said that the incision should have been first made at the place where the stones were felt; but it was decided not to do so, on account of the obscurity with which they could be felt lying under considerable tissue, which might, in the displaced position of the gall-bladder, be a part of the intestines or contain large vessels, and at the depth at which they were situated it would have been exceedingly difficult, if not impossible, to control the hemorrhage or repair the damage to the intestinal wall, should it have proved to be the intestine. Indeed, I seriously debated even abandoning any attempt to remove the stones at one time, on account of the difficulty of reaching them; and, on reviewing the case, I am inclined to believe that it would have been better to close up the abdominal wound, and trust to the possibility of the stones ulcerating into the duodenum, to which the gall-bladder was already closely matted.

The fatal issue in the man's debilitated condition was due to the shock of a prolonged operation and the moderate after-hemorrhage.

One other point demands notice. It is very evident that the hypodermic needle-point did not touch the stones, and it is somewhat doubtful to me whether the probe passed through the aspirator-needle did, judging from the depth at which they were found. But the sensation of scratching such a stone was so deceptive that all three of the resident physicians, as well as myself, were clearly under the impression that the probe certainly did do so, and we were fairly certain that the hypodermic needle also did.

A CASE OF ACQUIRED SYPHILIS WITH SECONDARY LESIONS, THE RESULT OF TATTOOING.

BY SPENCER TROTTER, M.D.

CASES of syphilis not acquired in the ordinary way, through sexual intercourse, are so rare comparatively that the following one may prove of interest not only in its medical but also in its legal and moral aspects:

In September, 1884, Arthur K., æt. 18, a native of Missouri, was admitted into the lower surgical ward of the Pennsylvania Hospital,—service of Dr. Thomas G. Morton,—suffering with a suppurating wound in the fold of the left elbow, which had been done with a knife in January of the same year, had healed up, and then broken down again.

On examination, there were found scattered over the body patches of pustulo-squamous syphiloderm; the genital organs were found to be exceedingly small,—undeveloped, in fact,—and from his statement he rarely had an erection, and then very imperfectly, and never had had a nocturnal emission. There was neither history nor sign that there had ever existed any primary lesion on the genitals. His arms and forearms were tattooed with well-executed designs. He gave the following history.

In 1876 he was first tattooed, and since then off and on until March, 1884, when the last two pieces were executed on the left forearm. Previous to this the tattooing, which was done by different individuals, had never given rise to any sores or symptoms other than the slight irritation from the materials employed. One of these last two pieces was the figure of an elephant, which was done by a man who *wet the needle-holder in his mouth* to outline the design, and then worked in the vermilion and India-ink. This was followed in several weeks (he did not remember the exact time intervening) by a distinct, suppurating ulcer, which lasted for some time. Two months after this (in May, 1884) the cicatrix in the fold of the elbow broke down into an ulcer. In June (1884), three months after the primary lesion, a patch of pustulo-squamous syphiloderm appeared on the back, and since then others have developed on other parts of the body.

The patient does not remember having the roseolar and papular eruptions of the early secondary stage, but "copper-colored" maculæ were observed on the trunk, and the half-arches and velum palati showed the condition characteristic of secondary syphilis. An axillary and an epitrochlear bubo were found on the left side, and by a careful inspection with a lens a distinct scar, the cicatrix of the chancre, was found in the saddle of the ele-

phant figure. The patient was placed on the protiodide of mercury in combination with an iron salt, but left the hospital in a short time of his own accord, very slightly improved.

This case is one of peculiar interest, inasmuch as we are able to draw a positive conclusion as to the source and point of infection of syphilitic poison by excluding the almost undeveloped genitals as a factor in the acquisition of the disease.

Undoubtedly a "mucous patch" or some other form of syphilitic lesion existed in the mouth of the person who tattooed our patient last, who *wet the needle-holder to outline the design by putting it in his mouth*, for his tattooing was the only one followed by a distinct "sore," which was without doubt a chancre, as it was followed by secondary lesions.

PHILADELPHIA, October 16, 1885.

NOTES ON THE NEW ANTISEPTICS, HYDRONAPHTHOL AND THE POTASSIO-MERCURIC IODIDE.*

BY R. J. LEVIS, M.D.,

Surgeon to the Pennsylvania Hospital and to the Jefferson College Hospital.

THE following are the claims made for the newly-discovered antiseptic, hydronaphthol:

It is at least twelve times as effective as carbolic acid, and is entitled as a true antiseptic to occupy a position in the comparative tables next to the mercuric bichloride.

It is thirty times as potent as salicylic acid, sixty times as effectual as boric acid, and has six hundred times the antiseptic power of alcohol.

Hydronaphthol is soluble when placed in cold water to the extent of one part in two thousand. It is soluble in hot water in the proportion of one to one hundred; but when the water becomes cooled to ordinary temperatures a precipitate occurs, leaving a solution of one to one thousand. In this strength of one to one thousand it permanently prevents the development of the germs of putrefaction in all putrescible fluids.

Whilst the true antiseptic or *inhibitory* action of hydronaphthol in such cold aqueous saturated solution is perfect, its germicidal and proper disinfectant power is ineffective. For the destruction of already existing germs, such as have a tenacious vitality, as those of anthrax bacilli and pathogenic micrococci, it therefore cannot be relied on. As to its action in this regard, as compared with carbolic acid, it should be remembered that a ten-per-centum carbolic solution is required,—a strength practically improper in wound-treatment. In ordinary antiseptic practice, carbolic acid is valuable only on account of its inhibitory action.

The first use of hydronaphthol as an antiseptic was by Dr. G. R. Fowler, of Brooklyn, to whom the profession is indebted for its introduction to practical surgery. My own experience with the antiseptic action of hydronaphthol in the wards of the Pennsylvania Hospital and in private surgical practice confirms his observations, as given in his recent articles in the *New York Medical Journal.*

Hydronaphthol is a grayish substance, in the form of crystalline laminæ having a slightly aromatic taste and odor. It is soluble freely in alcohol, ether, chloroform, glycerin, benzole, and the fixed oils.

In the aqueous saturated solution of one to a thousand it is absolutely unirritating, and has no toxic action, either local or systemic, is free from unpleasant odor, and has no injurious action on metallic instruments or on clothing-fabrics.

Besides its use in aqueous solution, I have used it in the form of a powder diluted, preferably with the oxide of zinc in the proportion of one to fifty.

I believe that hydronaphthol may well displace carbolic acid from practical surgery.

The potassio-mercuric iodide is four or five times as powerful as a true germicide or disinfectant as the mercuric bichloride. For such use it is effective in aqueous solutions in the proportion of only one to twelve thousand.

The potassio-mercuric iodide is made by simply dissolving equal quantities of the biniodide of mercury and the iodide of potassium in distilled water. The solution is evaporated, and there remain yellow, needle-like crystals of the potassio-mercuric iodide.

In the use of such dilutions of this powerful antiseptic, local irritation is entirely avoided, and the risk of producing the

* Read before the Philadelphia Academy of Surgery, November 2, 1885.

constitutional effects of mercury is greatly diminished.

The introduction into surgical treatment of these two remarkable and powerful substances, hydronaphthol and the potassio-mercuric iodide, will do much to overcome some of the objections and inconveniences of antiseptic practice.

TWO CASES OF LIGATURE OF THE DORSALIS PEDIS ARTERY FOR HEMORRHAGE.

BY CHARLES A. SEWALL, M.D.,
Acting Assistant-Surgeon, United States Army, Post-Surgeon, Fort Selden, New Mexico.

THE following cases occurred at Fort Stanton, New Mexico: *Case I.*—Manuel Truxillo, Mexican. I found the patient bleeding profusely from a wound over the instep, caused by having cut himself with an axe ten days previously. After removing the wrappings, which were saturated with blood, I attempted to tie the bleeding vessels in the wound by enlarging the incision, but the hemorrhage was so alarming it was thought best to ligature the dorsalis pedis artery. This vessel was readily exposed and tied just below the annular ligament. The ligature came away on the seventh day, and on the twelfth after the operation the wound had entirely healed. No anæsthetic was administered.

The second case occurred in a soldier. Private W., Sixth Cavalry, while cutting wood for the garrison ten miles from the post, cut his foot severely with an axe over the instep. Although the soldiers, his comrades, used various methods to stop the bleeding, when brought to me at the hospital the man had fainted, had a rattle in his throat, and indeed was almost moribund. Hypodermics of ether and brandy were given every half-hour until about twelve had been taken, and a large enema of brandy and beef-tea was introduced into the rectum, as extreme nausea forbade the administration of stimulants per os. An Esmarch's bandage controlled the hemorrhage temporarily.

The following day Assistant-Surgeon Marcus E. Taylor, United States Army, who had been absent from the post at the time of the injury, returned, and tied the dorsalis pedis artery under an anæsthetic. An attempt was made to tie the bleeding vessels in the wound, as in the first case, but without success. A drainage-tube was introduced, and healing proceeded in the usual felicitous manner common to all wounds at Fort Stanton, owing, doubtless, to the high altitude (six thousand one hundred and fifty-one feet) and pure dry air. Antiseptic precautions were taken in both operations and in the subsequent dressing of the wounds. These two cases occurred within two weeks of each other, and from this coincidence my attention has been drawn particularly to wounds of this region,—the dorsum of the foot. From an investigation into the anatomical relations of this class of injuries, we find that they are surgically important for two reasons,—first, the prominent position of the part renders it particularly liable to injury from chopping-instruments; and secondly, owing to its vascularity, a cut—at any point—could lay open almost a net-work of vessels.

When we remember that the dorsalis pedis artery feeds no less than four fair-sized arterial trunks,—viz., the tarsal, metatarsal, dorsalis, and hallucis,—and communicating, besides inosculating by the last-named vessel with the external plantar, to form the plantar arch, and that these vessels have branches ramifying in various directions, particularly the metatarsal, with its digital branches, we cannot but admit that hemorrhage in this locality is a serious accident, and that it will be the best course to pursue in the majority of instances to "make assurance doubly sure" by tying the main source of local arterial supply, as the only hope for its complete suppression.

A CASE OF OBLIQUE HERNIA OF THE OVARY.

BY CHARLES BAUM, M.D.

MRS. P., æt. 36, married, is of English descent. Although nervous and spare, never robust, she has not suffered from disease, except dysmenorrhœa of moderate severity. She has had one abortion, and is the mother of three large, healthy children, the last labor having occurred two years ago: it was marked by partial placenta prævia. Since this labor she has complained at times of dragging pains in the pelvis, but was not prevented from performing her household duties. Nausea and a tendency to syncope accompanied these pains, which were always more severe at what would have been the menstrual

periods. The babe was weaned when thirteen months old. Menstruation recurred ten months after the labor, and each epoch thereafter was marked by nausea, vertigo, uterine tenesmus, and a sensation as if the uterus were being dragged from the pelvis by violence. For about three weeks a swelling had gradually been enlarging in the left groin, until a limping gait was assumed for relief of the dragging pain in the pelvis. When I examined the parts, twenty months after the labor, an evenly-smooth, olive-shaped swelling, about one and one-half inch in length by one inch in width, occupied the left inguinal canal. None of the signs of inflammation were present. Pressure on the mass provoked nausea, while traction caused an increase of the dragging pain, which was referred to the uterus. The ovary was reduced in a few minutes by taxis, unaided by anæsthesia. A truss was directed to be worn, but this advice the patient neglected.

One month later, just before her menstrual period, the ovary again was found occupying the inguinal canal, and while in this situation menstruation occurred, causing great swelling, tenderness, and pain, with some redness in the left groin, accompanied by frequent emesis, prostration, and tearing pains, referred to the uterus. When the period had been completed, spontaneous reduction of the ovary occurred.

630 North Broad Street, Philadelphia.

NOTES OF HOSPITAL PRACTICE.

CHICAGO MEDICAL COLLEGE HOSPITAL.

SERVICE OF WALTER HAY, M.D., LL.D.,

Professor of Nervous and Mental Diseases, and of Medical Jurisprudence.

Stenographically reported by William Whitford, M.D.

CEREBRAL CONGESTION—PETIT MAL.

GENTLEMEN,—Our first patient presents all the appearances of health. She says that her mother was strong and robust, having had nine children, all in good health; her father, too, was hearty, powerful, and robust. As far as can be ascertained, her ancestry was very healthy. This is important, because it justifies us in excluding any hereditary taint or proclivity. It also excludes the existence of the neurotic diathesis as a predisposing cause of disease. The next things to be considered are the patient's age and history. She is 16 years of age. She is well developed, and has all the appearances of good health. Two months ago, we are informed, she menstruated for the first time, and about three weeks ago she menstruated again scantily. While it is evident that the girl's nutritive processes are active and vigorous, at the same time the uterine functions seem to have been dormant. The evidence goes to show that, coincident with the first effort at the manifestation of its functional energy by the uterus (which manifestation was difficult and feeble, not from organic disease or obstruction in the ordinary sense of the word, not from any uterine disease, but simply because of inefficient, gradual, tardy assumption of its physiological functions), our patient was suddenly seized, while at work, with giddiness, followed, not immediately, but speedily, by loss of muscular power and of consciousness,—in fact, there was a suspension of all the nervous functions,—during which condition she remained, we are told, *perfectly still*, with a flushed face. After about twenty minutes, as near as can be learned, she recovered consciousness. This attack was followed by another somewhat similar just about the time of the next menstrual period, or shortly after it, and this one by another.

We have here the evidence of increased intravascular pressure, which was not relieved by the customary discharge from the uterus, and we have also probably an explanation of the insensibility. After a superficial analysis of the case, the diagnosis "epilepsy" is plausible. Let me call your attention to the differential diagnosis of epilepsy. Epilepsy has for its essential phenomenon spasm, indicating increased irritability in the medulla and pons, expressing itself in reflex spasms, the first spasmodic phenomenon expending itself upon the cerebral blood-vessels. This is the first morbid phenomenon in an attack of epilepsy, the vaso-motor spasm being indicated by extreme pallor of the face, dilatation of the pupils, and insensibility. The spasm in epilepsy may not involve the spinal centres or manifest itself in the muscular apparatus. In this case we may have no general convulsion, but simply epilepsy in the form of what is known as "petit mal." In addition to this unconsciousness, we may have spasms of the muscles of the neck, compression of the cerebral veins by the spasmodic action of

the muscles, obstruction to the return of venous blood from the sinuses of the brain to the heart, and, as a consequence, speedily supervening epileptic coma, upon the occurrence of which the spasm ceases. Now, inasmuch as respiration is entirely arrested in an attack of epilepsy, the convulsions cannot continue longer than a minute and a half, because death would ensue. In this case, however, we have a narrative of insensibility extending to twenty minutes, her parents having fixed that time on three different occasions. Had they said an hour, I should have regarded it with some degree of doubt as being merely a guess, but they fixed the time at twenty minutes. They probably carefully observed the time of the insensibility during the attack. *True* epilepsy could not exist for such a length of time. In this case there were no convulsions of the muscles, no vaso-motor spasm, because we are told that her face was "bright red," but there was unconsciousness due to increased intracranial pressure or congestion of the brain. There should have been a congestion of the uterus at that time, and that congestion should have been relieved by the menstrual process. Our patient, as is the rule with women in a healthy condition, makes more blood than is necessary for nutrition, and the excess of that blood should be eliminated every four weeks by the uterus; but in this case the excess was not discharged. Moreover, her attention was being occupied by a certain amount of brain-work: hence the brain was in a state of physiological activity, and the blood was attracted towards it, consequently there was congestion of the brain instead of congestion of the uterus. For this reason, and acting upon this theory, I prescribe the following: Fluid ext. ergot, 25 grammes; water, 25 grammes. M. Sig.—Take teaspoonful at bedtime.

There is no drug which will so promptly and efficiently contract the blood-vessels in the nerve-centres as ergot. It can very rapidly induce cerebral anæmia. The indication in this case is to keep guard over the cerebral circulation. The case is not epileptic just now, but might be developed into such a state very readily. The frequent recurrence of increased vascular pressure within the brain might induce permanent dilatation of the vessels in the medulla and pons, and the dilatation might establish, by reason of its increased vascularity, a condition of increased irritability in the convulsive centres, which, constituting a predisposing cause, might establish the condition known as hystero-epilepsy, related to the menstrual function, and, coincident with it, the menstrual function appearing and interposing as an exciting cause.

In an epileptic paroxysm, with contraction of the blood-vessels and pallor of the face, the application of nitrite of amyl to the nostrils will result in a flushing of the face. The drug will overcome the vascular spasm in the brain, increase the intravascular pressure, and arrest the paroxysm instantly. But nitrite of amyl applied to a case like this, with vascular pressure in the brain already increased, as indicated by the red, flushed face, unusual congestion or possibly a hemorrhage within the brain would be readily induced. The vascular pressure would be increased still further by reason of the exhaustion of the vaso-motor energy, and it might be sufficient to precipitate hemorrhage, or it might be sufficient to overcome the vaso-motor resistance altogether without rupture, and thus occasion a fatal arterial congestion of the brain.

A point of practical importance in connection with the treatment of this case is the color of the face. If you have a patient with a pallid face, presenting a condition of syncope without convulsions, never throw water on her, because it is simply a barbarism; but let her lie down, and the unconsciousness of syncope will give place to the consciousness of restored circulation in the brain. Place your patient in a horizontal position, lift the feet, and the face will flush instantly. If the patient has a flushed face, such as this girl presented, apply cold cloths or ice to the elevated head, to induce by their reflex effect contraction of the blood-vessels and relief of the pressure within the brain. It is very probable that this patient will continue to have these attacks of cerebral congestion until the menstrual function is properly established.

PETIT MAL.

I will call your attention to the marked contrast between the predisposition in this case and the other. Our other case was a girl with a flushed face, apparently robust and healthy, and without any hereditary taint; but here we have a patient 32 years of

age, whose mother was insane, in all probability, for eleven years. On the father's side, we are informed that there was an uncle subject to similar attacks. This presents to us the neurotic diathesis by inheritance. She also has unconscious periods. The "spells," as she terms them, first developed when our patient was but two years of age, about which time she had an attack of measles. Now, there are some points of interest connected with these attacks to be distinguished from typical cases of epilepsy. You recognize the epileptic character of the disease, but it is not a typical case of epilepsy. It is a case of the non-convulsive form. We have no history of falling, struggling, or frothing at the mouth, but there is a peculiar expression about the eyes: they look wild and glassy. She does not fall very often during these attacks, but, as she expresses it, "works with her hands." Now, that may be spasmodic or automatic. It is not uncommon for the convulsive paroxysms in epilepsy to be substituted by a type of mental perversion, delirium, or epileptic mania. This is an instance, in all probability, of what I described to you as petit mal,—the non-convulsive form of epilepsy,—the seizure marked by premonitory symptoms, by the "aura epileptica," as it is termed. This is a perversion of sensory innervation, apparently peripheral in its origin, and pursuing a centric or centripetal course, usually beginning in the stomach and creeping up gradually to the head, following which is insensibility. This is characteristic of the true epileptic seizure, although this is not a typical case, as it is the non-convulsive form. The contrast between the two cases is very marked.

The prognosis in this case is bad. The woman in all probability has inherited a diseased brain—structurally and organically diseased—from both sides of the house. "Like produces like," always and everywhere.

A fruitful source of epilepsy is chronic alcoholism in parents. It is probable that the father died from some cerebral disease. She tells us that the doctors said there was a "rush of blood through her father's head after a surgical operation, and that his face was red for some hours after death," indicating increased vascular pressure. Here we have another source of the neurotic diathesis, the predisposing agencies and influences to establish it in this woman. It is clearly established, not only by the history as related, but by her present appearance and expression of countenance. This has become habitual, and alone would induce me to suspect the existence of epilepsy, even if there were no history of the case.

If we can keep the paroxysms under control we may accomplish some good to the woman, but I scarcely look for a complete recovery or any material benefit in this case. After the disease has existed for a period of thirty years, organic changes have probably taken place in the brain which are irremediable. For this case we prescribe the following:

℞ Potassii iodidi, 5 grammes;
Potassii bromidi, 25 "
Ammonii bromidi, 15 "
Ammonii carbonatis, 3 "
Infus. gentianæ, 200 " M.
Sig. Teaspoonful before each meal and at bedtime.

TRANSLATIONS.

PROSTATIC ENLARGEMENT.—Dr. Guyon advises the adoption of the following rules by those suffering with prostatic trouble:

1. Avoid all causes of chill, general or local.

2. Absolutely forbid excess in eating and drinking; seek to prevent abuse rather than to proscribe the use of injurious food and drinks. It is not only excesses in stimulating or alcoholic drinks that the prostatic subject should avoid, but even excesses in drinks the most inoffensive in themselves. It is for this reason that advice to adopt the hydro-mineral treatment should be given only with great circumspection.

3. Avoid voluntary and prolonged retention of urine in the bladder: in resisting the desire to urinate, these patients expose themselves to serious accidents,—retention, cystitis, etc.

4. Sexual indulgence should be moderate, observing the precept *Non morari in coitu.*

5. Keep in mind the evil influences which are exerted at night by the horizontal decubitus and the prolonged immobility. At night avoid a long rest in bed.

A walk of fifteen minutes up and down the room may be taken before retiring, and on rising, with great benefit. In the daytime, in order to prevent contracting sedentary habits, activity is recommended, avoiding fatigue in walking or riding. Constipation is best treated without drastics: a large lavement, warm or cold, taken on rising in the morning, exercises an action at once evacuating and derivative. Often an emollient enema is useful at night, which is to be retained.

6. The skin should be carefully guarded and kept in good condition by dry frictions, massage, and warm baths.

Dr. Tuffier (*Thèse de Paris*, 1885) has shown that in patients with hypertrophy of the prostate the bladder and kidneys are chronically congested, and are thus on the verge of inflammation.

The treatment of prostatic enlargement varies with the period of the malady. In the first period a vigorous hygienic treatment only is needed; catheterism should be forbidden. The second period calls for the catheter to accomplish the evacuation of the bladder. This will have to be repeated in accordance with the degree of the retention. Sudden retention requires antiphlogistic treatment before catheterizing. In difficult cases hypogastric puncture (aspiration of the bladder) may be practised. The next day the catheter may again be used with facility. If it remains difficult, a sound may be retained. The evacuation should be gradual and antiseptic.

Strictures of the urethra may be the site of congestions which bring about a transitory difficulty of micturition or complete retention. In this case the obstacle is found at the level of the stricture. This is a grave complication, and may require aspiration of the bladder, where other treatment has failed.

The *rôle* of congestion in the diseases of the urinary passages in women is also very important. The vascular connection of the uterus and bladder predisposes the latter to all the congestions occurring normally in the uterus. Vesical affections are aggravated at each menstruation and during pregnancy. Certain uterine affections lead to a chronic congestion of that organ, and, consecutively, to congestion of the bladder. The resulting urinary troubles, in such cases, disappear after the treatment of the disorder of the uterus alone.—*Revue de Thérapeut. Méd.-Chir.*

Intramuscular Injections of Metallic Mercury in Syphilis.—At the Grenoble Congress, Dr. Luton, of Rheims, read a communication, of which the following is a *résumé*:

1. The muscular tissue offers a way, preferable to the cellular tissue, for the absorption of metallic mercury.

2. This absorption is proved (*a*) by the therapeutic effects, (*b*) by the production, possible but not constant, of mercurial stomatitis, and (*c*) by experiment on animals.

3. Sulphur, given in an electuary, in a dose, at the least, of five grammes daily, constitutes a remedy for mercurial sore mouth far superior to chlorate of potassium.

4. The amount of metallic mercury, at the beginning, should be one gramme at most, taking into consideration, in repeating the injections, its value in bichloride (1 gr. to 1.354 gr.).

5. The advantages of this method are efficacy, the protection of the digestive tract, and the readiness of giving the remedy at regulated intervals.

6. The intramuscular injections of metallic mercury are at present recommended only for grave and chronic cases of syphilis at the period of transition and in the tertiary stage.—*La France Méd.*

Cocaine and Resorcine in Whooping-Cough.—Professor Moncorvo has advocated, in several published communications, the use of resorcine in whooping-cough as a local parasiticide and antiseptic application to the laryngeal mucous membrane. He further advises the preliminary employment of cocaine solution (ten per cent.). Not having any specific action upon the germs (?) of the disease, cocaine by itself is not curative, but as an adjuvant it has great value in reducing or removing the excitability of the pharynx, and in facilitating the topical applications of the germicide agent.—*Bull. Gén. de Thérapeutique*, September 30.

Topical Application for Neuralgia.—

EDITORIAL.

ALTERATIONS IN ARTERIES AFTER THE APPLICATION OF LIGATURES.

FEW among the many active medical societies of Philadelphia have accomplished results that can be compared with those of the Pathological Society. Since its organization in 1857, its career has been, with the exception of a brief period during the height of the excitement and anxiety attending the civil war, one of uninterrupted activity and usefulness. A new departure dating back a few years, by which specially-prepared papers have been presented at the semi-annual meetings, has led to most gratifying results. For some time these papers were read by active members of the Society, and added to the local interest in the proceedings as well as to the value of the Transactions. Important contributions from the pens of Drs. Cohen, Seiler, and others will not soon be forgotten. More recently the Society has had the good fortune to secure for these semi-annual meetings papers and addresses from active workers in pathology outside the city, and is under obligation to Delafield, of New York, and Sternberg, of the United States Army, for papers of great intrinsic value and of the widest interest as embodying the results of pathological research not only original, but also essentially American. To this list is now to be added an important paper by Professor J. Collins Warren, of the Medical Department of the University of Harvard, read at the last meeting. It is entitled "A Comparison of the Changes in Arteries after Ligature and in the Ductus Arteriosus and Umbilical Arteries after Birth."

This article, which is the result of a long series of personal studies by its author, presents views in some respects wholly at variance with hitherto accepted teachings. Dr. Warren found the earliest changes after the ligature of an artery in continuity to be the formation of a thrombus in the vessel, and the development of a mass of inflammatory tissue or callus around the point of ligature externally. No perceptible cell-action can be observed on the inner wall with low powers during the first week, although occasionally a limited proliferation of the endothelial cells near the point of ligature can be seen with high powers, and a few wandering cells may be found to have penetrated the walls of the vessel at the same point.

In the second week, the bundle of fibres of the adventitia which was held by the knot becomes absorbed, and the two ends of the vessel retract slightly from each other, leaving the ligature embedded in and partly disintegrated by the granulation-cells. At this time the walls of each portion appear to form a complete *cul-de-sac*, as though the healing process were complete. But this is by no means the case, for the beginning of the second stage is marked by the unfolding of the ends of the vessel, the walls of which now separate somewhat after the manner of the opening of a bud, permitting the entrance of a considerable quantity of the granulation-tissue. Disintegration of the thrombus follows, with the formation of an internal callus protected from the blood-current by a small fragment of clot. The ligature may be wholly disintegrated and absorbed, or it may become encysted, or, finally, a small abscess having been formed at its site, the fragments of thread may be discharged through a sinus opening externally. The second stage is completed when the internal growth has reached the neighborhood of a branch. The external callus, which, as in fracture of the long bones, is merely provisional, is ab-

sorbed, and eventually the two ends of the vessel are connected by a slender cord of varying length, the walls being slightly separated by a cicatrix consisting of connective tissue externally, inside of which is another layer consisting largely of unstriated muscular fibres, the surface being covered within by a new endothelium. We have here a scar made up of three layers, resembling closely the three walls of the vessel. A somewhat different series of changes is seen in the large vessels of amputation-stumps. At first the end of the vessel is embedded in granulation-tissue, and contains a thrombus of varying length. In the second week marked changes are observed in the intima, extending some distance from the point of ligature. After several months, the vessel is found in the form of a cord running from the first large branch to the cicatrix of the stump. This cord laid open shows the walls preserved, its interior filled with new tissue in which are spaces occupied by one or more vessels, the condition resembling that known as obliterating endo-arteritis. A comparison of these two modes of healing with the changes seen in the arterial system after birth shows certain resemblances in the two processes.

The ductus arteriosus at the time of birth, in certain important respects, differs in structure from the aorta and pulmonary artery. The media is much thicker than in either of these vessels: it is thrown into irregular folds, which are increased at the time of birth. The outlines between the different layers are less marked than in the walls of other vessels. The lamina elastica is indistinct, and in places apparently wanting. The media consists chiefly of longitudinal layers of muscular fibre, a few circular bundles existing in the outermost layers. A few weeks after birth the greater portion of the walls of the ductus undergo hyaline degeneration, the outer or circular fibres of the media alone remaining. There is at this time an active growth of long, spindle-shaped cells, with staff-shaped nuclei at the edge of the media bordering on the opening into the aorta; there is also thickening of the intima. Eventually the hyaline tissue becomes absorbed, and is replaced by a band of fibres continuous at each end with the media of the large vessels. At the aortic end, in a longitudinal section, the media is seen slightly separated at the point of the cicatrix, and between the two and continuous with them are the longitudinal fibres of the ligamentum arteriosum. In the centre of the depression marking the site of the cicatrix a small vessel is given off into the axis of the ligament, where it either loses itself in a capillary net-work or becomes continuous with a similar vessel coming from the pulmonary artery. Dr. Warren pointed out in detail the points of resemblance between the changes in the ductus and in the hypogastric artery and those seen in the main trunk of an amputation-stump. A slight portion of each vessel is destroyed; both retract, and are attached to the terminal cicatrix by a band of fibrous tissue; both remain as pervious vessels with thickened coats and narrow calibre. In both the process is not unlike that seen in so-called obliterating or compensatory arteritis. Dr. Warren, however, regards "arteritis" as a term hardly applicable to the changes taking place in normal arteries after birth. Nor can the alterations which are developed through the whole length of a large vessel extending a considerable distance from the original seat of inflammation be strictly regarded as of an inflammatory nature. He is disposed also to regard the obliterative growths in terminal arteries in widely-removed portions of the body of the same individual as not of an inflammatory nature, but rather as a secondary and formative process, closely connected with disturbances in the mechanism of nutrition, designed to adapt the vessels to a diminished blood-supply.

THE USE OF ARSENIC IN CHOREA.

ONE of the strongest arguments against the organic-lesion theory of chorea is found in the fact of the remarkable influence exerted upon the disease by the administration of arsenic and by rest. Even occurring in the lower animals, it has been found to be controlled by this remedy. Fowler's solution has been administered hypodermically to a choreic dog with success. In London, at a recent meeting of the Harveian Society, Dr. W. B. Cheadle reported, as the result of an experience in one hundred and sixty cases clinically observed during the last eight years, that the arsenical treatment materially shortened the duration of the disease, cases using it terminating in recovery within five weeks, as the rule; whereas with no treatment they extend from eleven weeks to a year or more.

Its value was recognized by Todd; but, like others since his time, he dreaded its toxic effects. The form in which it is best used is in combination with iron, and Dr. Cheadle prefers the ordinary liquor arsenicalis (liquor acidi arseniosi, U.S.P.) in ordinary doses with tincture of ferric chloride. A series of cases treated with arsenic recovered, on the average, in twenty-nine days; in others, treated with other remedies, its course averaged forty days. Although the remedy is usually well borne in the doses in which it is employed, yet Dr. Cheadle noticed a hitherto-undescribed effect when the arsenic is given to young children, in the form of a bronzing of the skin resembling Addison's disease. The discoloration was most marked on the body in the flexions of the large joints, but not on the face. It afterwards faded away; although in one case the process was very slow. The pigmentation was similar to that produced by chronic congestion of the skin, and was not analogous to the metallic deposit in argyria. The results reported by Mr. Cheadle* are confirmatory of the observations of others; and, while they indicate that arsenic is one of the most efficient of our remedies in the treatment of chorea, it is not to be inferred that the remedy is to be used to the exclusion of chalybeate and other tonics, which have also been found useful as adjuvants.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THE American physician who for the first time undertakes to look through the many hospitals and medical schools of London must find his task somewhat bewildering. Such, at least, has been my experience, notwithstanding that I brought with me letters of introduction to half a dozen prominent members of the profession here, who have kindly afforded me all the assistance that could be expected of them. The local guide-books mention upwards of fifty hospitals, and I have run across at least one very important institution of the kind which most of them do not describe,—to wit, the Central London Throat and Ear Hospital, of which Mr. Lennox Browne is the senior surgeon. Of medical schools, great and small, there are fully half that number. In fact, nearly every hospital of any consequence has a school connected with it; many of the smallest even have each a little coterie of students who accompany the visiting physicians and surgeons on their rounds through the wards, and have the exclusive right to study the patients therein treated. This system of decentralization doubtless has its advantages for the students, but it has also very manifest disadvantages. The largest city in the world, with a population of about four millions and a vast amount of clinical material, ought to be a centre of medical education second to none. With such an affluence of material, and numerous resident teachers ranking among the first in their respective specialties, it is remarkable that London has no polyclinic or post-graduate school, but sees every year three or four hundred American physicians alone, to say nothing of physicians from other English-speaking countries, including Great Britain itself, pass its very doors and go to Vienna, Berlin, Paris, and other Continental cities, where they have to encounter the difficulties of a foreign tongue in addition to those of the medical studies they desire to pursue. Some day there will probably be a change in this respect, but it is not likely to come soon. Conservatism stamps

* British Medical Journal, October 24.

everything here, and the profession, even if unitedly desirous of centralizing medical education, could not very speedily bring about the necessary changes in the hospital regulations.

Though the schools nominally opened last Thursday, they are not yet fairly settled to the work of the session. Some of the more famous professors, notably Sir Joseph Lister, who is one of the staff at the King's College Hospital, have not yet returned from their vacations. Mr. Bryant, of Guy's Hospital, delivered his first lecture yesterday. His subject was clinical investigation, and, along with much other excellent advice, he earnestly counselled the exercise of the utmost gentleness in all examinations and manipulations.

At the Royal Free Hospital on Gray's Inn Road, connected with which there is a medical school for women, I saw a very neat ovariotomy done on Tuesday last by Mr. William Rose. The tumor was of moderate size, and there were no adhesions. The incision made measured only about four inches. He operated under the carbolic spray, and used the entire Listerian dressings.

Dr. W. S. Playfair is the only gynæcologist or surgeon in London, so far as I can learn, who does the Emmet operation for laceration of the cervix uteri. One of the oldest and most eminent of English teachers in this department of medicine was examining cases the other day before a ward-class and in my presence. One poor woman placed on the table presented a typical case of an old laceration of the cervix, with much swelling of the entire organ, as is usual. It was pointed out to the class as a hypertrophied cervix, and orders were given to have it cauterized. In a subsequent conversation with the professor I found that he was a total disbeliever in Emmet's operation; but what seemed strange to me was that even the fact of the existence of a laceration in such cases was entirely ignored. This is astonishing, when the true state of the case can be so conclusively demonstrated by simply bringing the separated lips together with two tenacula, when the so-called ulceration and most of the hypertrophy disappear.

Last evening I had the pleasure of hearing a very notable discussion at the meeting of the London Obstetrical Society. There were, first, reports by two young gentlemen of peculiar obstetrical cases. One of them described as an extra-uterine pregnancy a case in which both the fœtus and placenta were finally delivered by the way of the uterus and vagina. There had been a lump in the right groin, with symptoms of pregnancy which ceased about the third month. He dilated with sponge tents, and, examining under chloroform, found an empty uterus which measured only two and one-quarter inches. Shortly after this procedure labor came on, and the fœtus and placenta were in due time delivered *per vias naturales*. The reporter was very positive that it was a tubular pregnancy, and that the products were discharged first into the uterus, and thence in the usual way. Some of your readers will doubt this, and so did the wise old heads of the Society. A committee was appointed to investigate the case, and it was particularly insisted that the woman herself should be examined, to ascertain if she might not possess a double uterus.

After this came the *pièce de résistance* of the evening, a paper by Dr. Matthews Duncan on "Lupus of the Vulva." At a previous meeting of the Society, two or three months ago, he had contributed a paper upon the same disease, and this was a continuation of the subject. Four or five cases were narrated of a peculiar affection characterized by elephantoid tumors of the labia and clitoris especially, but often involving the anus also, and showing a marked tendency to undergo ulcerative degeneration. The so-called urethral caruncles were considered by Dr. Duncan to be usually a form of his "lupus of the vulva." Numerous colored drawings representing the cases reported were passed around. The discussion was very spirited and interesting.

Mr. Jonathan Hutchinson, judging from the very full clinical histories and the illustrations, considered the lesions to belong to an aggravated and very intractable form of tertiary syphilis.

Dr. Playfair had seen elephantiasis in India, and when he met with the kind of cases described by Dr. Duncan he treated them as he would treat that disease, considering them practically the same.

Dr. Thin had made microscopical examinations of Dr. Duncan's cases, and had found the disease to be histologically similar to but not identical with elephantiasis. Neither was it syphilis or epithelioma. He found it to be different from those diseases both histologically and clinically. On the other hand, it certainly was not the lupus of dermatologists, —lupus vulgaris. He considered it a disease by itself, which merited a separate name, and could only be classed under the name lupus when that word was used in its old generic sense.

Dr. Duncan, in reply, stood his ground boldly; admitted that the disease he referred to was not lupus vulgaris, but, in his emphatic way, scouted the idea that it was either syphilis or elephantiasis. He announced his intention of reading a third paper upon the same subject at a future meeting.

It should have been stated before that among several other gentlemen who took an incidental part in the discussion was the venerable Dr. West, who was the predecessor of Dr. Duncan in St. Bartholomew's Hospital.

In several of the inaugural addresses at the opening of the medical schools last Thursday, mention was made of recent actions against physicians for certifying to the insanity of persons who were claimed to be sane. Some of these actions, it seems, went against the

physicians, who were mulcted in damages. The profession here is much disturbed over the matter, and it is generally agreed that medical men should all refuse to sign any certificate of insanity until the law is so changed as to protect them in so doing. Your very able London correspondent, Dr. Fothergill, has probably referred to this subject, and therefore it may be an old story to your readers; but you will pardon my calling attention to the fact, in this connection, that Dr. J. Kingston Fowler, in his address at the Middlesex Hospital, urged in forcible terms the identical views as to the relation of physicians to the confinement of alleged lunatics which were broached by the writer hereof in a paper contributed to the *Philadelphia Medical Times* nearly three years ago.* The argument he advanced was that physicians had not asked, and did not desire, to have imposed upon them the purely judicial function of deciding who should be restrained of their liberty on account of insanity; that however much dependence might be placed upon the testimony of physicians—especially upon that of experts in mental disease—as to the fact of unsoundness of mind, the final order for commitment, or at least for prolonged detention, of alleged lunatics should be issued by some magistrate or judge. This idea was elaborated by Dr. Fowler, who proposed, by way of meeting certain objections, that a physician's certificate should still be sufficient warrant for placing a patient under restraint, if need be, in an asylum, but that within forty-eight hours after such a commitment a magistrate should regularly investigate the case, with the help of a competent physician as an expert, and take the responsibility of either ordering his detention or of turning him loose upon the community.

Drs. Ringer and Murrell are still engaged in the very important work of testing experimentally, in the chemical and physiological laboratory, the value of various new drugs which from time to time are claiming the attention of physicians. They have just completed an analysis of the various preparations of pepsin, pancreatin, and malt extracts. Certain well-known American preparations, especially Fairchild's extractum pancreatis, have been found the most active; and, speaking of pharmaceutical matters, it was gratifying to find an American firm of only six years' standing—Messrs. Burroughs, Wellcome & Co.—to have fairly taken the lead among London pharmacists,—or chemists, as they are called here. Their preparations, and full lines of American pills for which they are agents, are now to be seen in nearly every fashionable chemist's shop.

BOARDMAN REED.

October 8, 1885.

* "The Insufficiency of the Laws governing Commitments to Insane Asylums," Boardman Reed, M.D, *Philadelphia Medical Times*, vol. xiii. p. 258.

NEW YORK.

AT the meeting of the County Society for October 26 the present officers were re-elected. Dr. A. Jacobi offered the following amendment to the by-laws, which was adopted unanimously:

"*Resolved*, That the *Comitia Minora* be directed to recommend no applicant for admission to membership unless he be a graduate from a medical college in good standing, or a licentiate of a regular unsectarian State or county medical society of this or any other State; or, if his diploma or license be of sectarian character, unless the applicant declare in writing his or her abnegation of sectarian principles and practice."

The Society wrestled with the question of how to compel delinquent members to pay their dues. With this view the following amendment to the by-laws was passed by a small majority:

"If any member shall fail to pay the yearly dues within thirty days after the fourth Monday in November, when the same shall become payable, it shall be the duty of the Treasurer to serve, in the manner in which notices in suits are required to be served on attorneys, upon each member so in default a copy of this by-law, and a notice to the effect that, unless such dues are paid within fourteen days thereafter, his name and the amount due by him will be reported to the Society at its next succeeding stated meeting, and entered upon the minutes; and if they are not so paid, the Treasurer shall report the same accordingly. At the next stated meeting of the *Comitia Minora* after the date of such report, the *Comitia* may, by order, without further notice, strike from the roll the name of any member continuing in default, and he shall thereupon cease to be a member of the Society; provided that, upon his written application explaining such default, and the payment of all dues to the date thereof, or provided that the *Comitia* unanimously remits the arrears, the *Comitia* shall have power to remit the penalty of this by-law."

The Secretary, in explanation, said that a similar by-law had been found to be very effective in the Bar Association of this city.

Fault has been found with the Medical Register which has been issued for some years by the New York Medico-Historical Society, it being thought especially that it should not omit the names of any of the members of the County Medical Society. Inasmuch, however, as the County Society (as indicated by the amendment to the by-laws proposed by Dr. Jacobi) admits to membership some who are graduates from other than regular medical colleges, the publishers of that Register think they are justified in their course. The outgrowth of all this was the following proposed amendment to the by-laws:

"It shall be the duty of the Secretary to prepare annually, and send to each member

of the Society, a register containing the names, addresses, and office-hours of the active members of the Society,—the register to be prepared at such time and in such manner as the *Comitia Minora* shall direct."

Dr. Jacobi thought it would be better to provide yearly for such a register by special vote rather than by by-law. There was also much other information which he would like to see in the register, and which was not contained in the Medical Register for the States of New York, Connecticut, and New Jersey.

Dr. A. L. Loomis was in favor of issuing a register containing the names of all legal practitioners in New York State and surrounding counties, and offered an amendment to the proposed by-law to that effect. Perhaps Dr. Loomis had in view, when he offered the amendment, to issue a register which would be valuable for general reference, which should not pretend to decide the question as to who were or were not regular practitioners by excluding the names of some who were nevertheless legally qualified to practise; and, being for general use among physicians of all classes, it would command a greater sale and be less a burden to the Society. It became evident, however, that the work and expense of such a register would be great, and it was therefore somewhat hastily decided to refer the whole matter to the *Comitia Minora* with power. What power the *Comitia* now has in the matter is probably a question in the minds of many; but no one imagines that it will decide at present to issue more than a register of the Society's membership.

WASHINGTON.

THE PUBLIC-HEALTH ASSOCIATION—MUSEUM OF HYGIENE—SMALLPOX INSPECTION SERVICE—WASHINGTON OBSTETRICAL SOCIETY—MEDICAL AND SURGICAL HISTORY OF THE WAR—PERSONAL.

WASHINGTON, November 4, 1885.

THE Committee of Arrangements of the American Public-Health Association is actively at work preparing for the coming meeting of the Association in December. The sessions will be held in Willard's Hall, attached to Willard's Hotel, where the headquarters of the Association will be. President Cleveland has been invited to attend the opening session, and has signified his intention of being present. The Commissioners of the District of Columbia will also attend, and Mr. Edmunds, the President of the Board, will make an address.

The rate of fare on all railroads south and west of New York, except the Chicago and Northwestern, will be reduced to two-thirds of the regular rate for the round trip for members.

After the adjournment, an entertainment in the shape of an oyster-roast will be tendered the visiting members and their friends by the local committee. It is expected also that President Cleveland will hold a public reception during the meeting.

At the Museum of Hygiene attached to the Navy Department, an elaborate series of experiments upon the siphonage of traps is now being made. The observations will soon be completed, and the results then made public.

A strict inspection of passengers and baggage is being enforced on the Canadian frontier to prevent the introduction of smallpox from across the border. It is believed that no infected persons have gained entrance to this country since the inspection service has been established. The service is under the general direction of the Supervising Surgeon-General of the Marine Hospital Service, but local appointments are made only upon the recommendation of the respective State Boards of Health.

The recent election of officers in the Washington Obstetrical Society resulted as follows: President, Dr. A. F. A. King; Vice-Presidents, Drs. W. W. Johnston and J. Taber Johnson; Recording Secretary, Dr. C. H. A. Kleinschmidt; Corresponding Secretary, Dr. S. S. Adams; Treasurer, Dr. G. B. Harrison.

The final volume of that monumental work, the "Medical and Surgical History of the War," is in an advanced stage of preparation, and is expected to be ready for the printer before the end of the year. Dr. Charles Smart, of the army, is writing the volume. It will be illustrated by many fine colored plates, like the other volumes in the series.

Dr. D. L. Huntingdon, of the Surgeon-General's Office, who has been absent in the West for about a month, has returned, and is again on duty here. G. H. R.

PROCEEDINGS OF SOCIETIES.

AMERICAN ACADEMY OF MEDICINE.

THE Ninth Annual Meeting of the American Academy of Medicine was held at the hall of the New York Academy of Medicine, October 28 and 29, 1885.

FIRST DAY, AFTERNOON SESSION.

The President, Albert L. Gihon, A.M., M.D., in the chair. The meeting was opened with prayer by Rev. Mr. Vandycke.

Dr. R. L. Sibbet, of Carlisle, Pennsylvania, read a paper on

THE STUDY OF MEDICINE AS A MEANS OF EDUCATION.

In Canada there were twelve medical schools, all of them regular. In the United States there were eighty-seven schools teaching rational medicine; the number of those engaged in teaching sectarian medicine was twenty-five. Sectarian medicine might be regarded as an American product, the first

school of the kind being established about fifty years ago in Pennsylvania. There was no need under any circumstances of rational medicine affiliating with sectarian medicine. The necessity of a preliminary and classical education was dwelt upon. As a rule, he said, preliminary examination was not required; classical studies were generally treated with indifference; the degree of M.D. was often conferred upon persons without even a knowledge of English grammar or orthography. No medical school in this country had adopted a higher standard than Harvard, yet here the standard was much lower than that required in the same institution for admittance to the freshman's department. The general practitioner, he said, if called upon in court to define the mind, could tell as little about the faculties of the mind as about the heavenly constellations. The author favored State medical boards of persons who would examine aspirants in general as well as in medical branches of knowledge.

MEDICAL SUPERVISION IN STUDENT-LIFE.*

Dr. Henry O. Marcy, of Boston, then read a paper on

THE CLIMATIC TREATMENT OF DISEASE, WITH THE ILLUSTRATION OF NORTH CAROLINA AS A HEALTH-RESORT.

Sanitation, in view of our knowledge of the influence of micro-organisms, had passed from the realm of theory and become based upon fact. Pure air, pure water, and pure soil now meant air, water, and soil free from infectious elements of disease. Enough was known of the bacillus tuberculosis to show that it could exist in all countries and climates, but its development was favored by cold, damp localities. Dr. Denison's climatic maps were shown, and some of his observations on the influence of altitude and other conditions of climate on the consumptive were quoted with approval. Clinical experience taught that, for those who were able to endure it, active out-of-door exercise in an elevated region exerted a beneficial influence upon the respiratory organs of the phthisical. The special advantages and physical features of the Blue Mountains of North Carolina, especially those about Asheville, were then pointed out. The temperature never became extremely warm or extremely cold; it seldom rose above 85° F. At places there was no frost during the entire year. The water was pure; the surroundings were beautiful and inspiring.

At 8 P.M. the President, Albert L. Gihon, A.M., M.D., read the following address on

WHAT IS MEDICINE?

The place of the Academy is not to be sought among the pathological, clinical, sanitary, and other national associations. It antagonizes none of these, but seeks to cement all into a compact unity.

Reasons for the slow growth of the Academy are:

In the first place, the fundamental condition of membership restricting Fellowships to graduates in medicine who have received degrees in letters in course.

As the co-operation of every educated man interested in the objects of the Academy is desirable, I am of opinion that the time has come when every limitation to Fellowship should be removed, except the solitary requirement that the candidate shall be in fact, as in title, "learned in medicine," and in all else that that implies; but would make it impossible for any one unfit or unworthy, though he come with an armful of diplomas, have subscribed to the most inflexible of codes, and no matter what faculty, society, or institution he may be delegated to represent.

Nominations should be accompanied by the fullest record-evidence, and be made long enough in advance—three, six, nine months, or a year—to enable the Council to determine each man's fitness.

A second reason why the Academy has not met with more pronounced sympathy and support is its necessarily hostile attitude to institutions and individuals who defy the principles of its constitution.

The Academy encounters a third obstacle in the lukewarmness of quasi friends,—some damning it with faint praise, and others exuberant in private but chary of public endorsement. An instance was given of a medical editor who could not follow his wish in this respect through policy; but the editorial columns of the medical press were usually pre-eminently high-toned. Publishers were inconsistent in permitting under the same cover advertisements of medical concerns, drug-factories, and proprietary clap-traps. Why should the business-venture of men who get up sham colleges be advertised in reputable journals? The *Medical Record* commends the resolution of the Florida Medical Association against the establishment of a medical college in that State. These encouraging signs of the times may be taken as offsetting the fact that thirty-nine of the eighty-seven regular schools in the United States are only fifteen years old, and twenty-one not over five. Trashy contributions from illiterate M.D.'s are published because they have been subscribers. If journals only reflect sentiment, let us ask ourselves the question, "What is medicine?"

If we look to this Academy for the answer, it will be limned clearly enough as the most profound and ennobling study which can engage the intellect of man. This, however, is not the popular idea. In their view, medicine is only something in a box or bottle prescribed by a man or woman who has acquired more or less skill in administering the partic-

* Will appear in the next issue of the *Times*.

ular remedy appropriate for each disease,—like other servitors whose offices are called for by the disagreeable incidents of humanity, only tolerated as a necessity. Sham aristocrats look down upon them; the plutocrat hires them as he does cook and coachman. In military and naval services he is sought to be degraded. The ministry of the suffering and afflicted is nowhere regarded as an outcome of the study of the stupendous and sublime mysteries of existence. In the national councils, in military and naval organizations, in civic administrations, who thinks of giving a *first* place to the physician, though his are the mental attainments which fit him best for counsel in all that concerns the welfare and progress of the human race?

The science of medicine involves the knowledge of everything that relates, however remotely, to the existence of man,—his place in nature, his origin, growth and development, preservation and continuance. The prevention and cure of those abnormal conditions which tend to his destruction are but one chapter in the volume which, coming near the end, cannot be read understandingly without the thorough comprehension and diligent study of all that precedes. Medicine is so far-reaching in its sources, and so concatenated with every other branch of knowledge, that he who would begin its study must first have drunk deep of the well-springs of human knowledge. Medicine is a science of such proportions that only a well-educated man can master it. Is this the view of it entertained by the profession at large? What are the facts?

Let us see how the profession is recruited. Ordinarily, a youth becomes a doctor, as he weds, from a whim; and those no longer young because, having failed in other occupations, they hope to make money by this,—knowing nothing of its responsibilities and requirements, without aptitude, ignorant and illiterate. Such a one goes to college, and as a first-course student listens to lectures on anatomy, practice, chemistry, surgery, etc., one after another, and without understanding a word of the technical language.

Seventy-nine colleges require evidences of preliminary education,—this only specious in most. Recent instances of illiteracy on the part of graduates before examining boards: "colume of murcury," "cours at Beleview," "anylitic," "assend," "admition," "diameter of the earth ninety-two thousand miles," "the Field of the Cloth of Gold some kind of tapestry," "an alterative acts like food on building up system and are favored in their action by stomachic or anything which arouses the system to action." Could the man who after graduation says "was began," and spells "gravatation," "femeral," "superating," "corpusels," etc., have ever comprehended the language used by his teachers?

Why should medicine be cheapened to every purchaser, and the college debase its teachings to their limited understanding? A collection of theses presented to American medical colleges during the last five years would be more entertaining than "English as She is Spoke." Only the utter ignorance of elementary chemical principles by the men who study medicine has made chemistry one of the seven chairs. It properly belongs to the academic course.

What only can medicine be to the ignorant members who are annually mustered into the ranks of the profession? To these men it can have no other aspect than that of a trade. They entered upon it as a money-making vocation; it was taught them as a source of pecuniary profit; they practise it for the fees they get.

Manifestly, then, medicine is not the same to all men, even medical men. If improper men can be excluded from national societies, why not from State, county, and city medical societies? This should be done for the protection of the community. Where a drug-clerk kills one victim by his carelessness, he saves a hundred by recognizing errors in physicians' prescriptions. Example from apothecaries' files:

℞ Solid ext. cannabis indicus, ℥j;
{ Syr. pruni Virg., } ℥j;
{ Syr. wild cherry, } ℥j;
Tr. opii, ℥iij;
Tr. opii camp., ℥j;
Aquæ, q. s. ℥iij. M.

Ft.—Tablespoonful doses to allay headache from coughing.

The debasement of medical education to the capacity of the ordinary purchaser of a diploma will eventually cause the profession to deserve the reproaches of its deriders. The public gauge the profession by the men with whom they most come in contact. The wise physician does not hesitate to say, "I do not know." The typical doctor affects an omniscience in inverse ratio to his knowledge.

Until the mystery of the first departure from health is made clear, all our therapeutics must be empirical and fundamental methods of cure all speculative. If we have not learned where disease begins, we have at least learned that the follies, vices, and errors of man have in their wake a multitude of ills, and these we can prevent; and the wise physician, learned in all that pertains to the normal life of the body, aims to protect it from those evil influences which experience has taught him will do it harm.

Preventive medicine has at last obtained recognition as the highest aim of the physician's art. It establishes new relations of the physician to the social system. It is not creditable to the intelligence of the age that in the department controlling internal affairs, among bureaus of labor, statistics, agriculture, education, etc., there is no bureau of public health. All sanitary service is the proper duty of med-

ical men. Preventive medicine has more to do than ward off epidemic visitations of great scourges. Its most important duty is to consider the impairment of health of growing children through the sanitary defects of our school system. The prevention of insanity, repression of crime, etc., are its legitimate duties. It is too much to expect antidotes for every microscopic germ. The tiny swarms around us are at once our friends and foes. If we do not antagonize them, they purify the air we breathe, the water we drink, the soil we tread, and prey upon our natural waste. Only our own folly causes them to turn and rend us.

Prone to hasty generalizations, we inconsistently denounce the doctrinaires who affect to believe in the panurgic virtue of similars, and ourselves find cure-alls in quinine, cocaine, germicides, etc.

Hence the greater need of impressing upon the tyro in medicine the fact that there are underlying principles never to be lost sight of. The old chair of Institutes of Medicine has gradually been supplanted by Principles and Practice. If I would banish Chemistry and Physics from medical colleges, I would establish a chair of the Philosophy of Medicine, and appropriately include the history of medicine, medical literature, medical jurisprudence, and medical ethics.

Reform is hampered by adherence to existing models. It will not do merely to establish adjunct chairs. The starting-point must be the requirement of a thorough preliminary education, to include an intelligent comprehension of the facts of chemistry and physics, of natural history and physical geography, of mathematics, languages, and belles-lettres. Four annual terms are necessary. Descriptive anatomy and the materia medica are enough for the first year; histology and practical microscopy, physiology in all its relations, and the mechanical processes of pharmacy, for the second; hygiene, general pathology, and general therapeutics, for the third; special pathology, special therapeutics, the philosophy of medicine, medical history, jurisprudence, and ethics, for the fourth. A fifth year to be devoted to clinical experience under supervision in public institutions.

Medicine has no need to rear its superstructure on any other foundation than the broad basis of fact. It has been dragged down to the level of commonplace occupations through the dissensions incited by the dogmas of theorists. There is no parallel between theological sects and medical "pathies." There is danger of too diffuse a system of differentiation. The tendency to degradation will be counteracted by more catholic views of morbid phenomena. The general practitioner will pay less heed to the artificial groupings of the nosologies, and look only to the grade of action exhibited by the pulse, the condition of the organic fibre, and the state of the secretions, no matter what name be given to the disease. When all physicians stand on the plane of higher medicine, there will be less tendency to diverge into extremist classes.

Is our estimation of medicine visionary, and have we sought the impracticable? Must we silence our voices because few care to hear, and cease our efforts because the task is difficult? Must we tread the beaten track lest we offend prejudices, antagonize pecuniary interests, and upset established orders? Not on this account shall we hesitate, if the truth be with us. The ethics of medicine rightly denounces fraternity with charlatans and quacks. Is our dishonor less if we degrade our noble profession by admitting to its rights and honors those who are ignorant, illiterate, and incompetent?

After the reading of the address the annual collation was served.

THURSDAY, SECOND DAY.

The Society was called to order at 10 A.M., by the President.

Dr. Thomas J. Turner, Medical Director of the United States Navy, read an interesting paper on

MEDICAL EVIDENCE.

It was followed by

REPORT ON LAWS REGULATING THE PRACTICE OF MEDICINE IN THE UNITED STATES AND CANADA,

by Dr. Richard J. Dunglison, of Philadelphia, and Dr. Henry O. Marcy, of Boston. It appeared that restrictive regulation regarding the practice of medicine had been made during the past year in only two States, —namely, Indiana and North Carolina. Letters from various prominent physicians throughout the States had been received, in most of which dissatisfaction was expressed at the present state of the laws regulating the practice of medicine.

HEALTH OFFICERS, ANCIENT AND MODERN.

Dr. Benjamin Lee, Secretary of the State Board of Health of Pennsylvania, read a paper with this title. The important position assigned to hygiene and State medicine during the past decade was evidence at once of an advanced stage of civilization and of dense and rapidly-increasing population. It indicated that the statesmen and the nation had at length reached that higher plane of political science in which they could appreciate Lord Beaconsfield's statement that "the health of the people is the first duty of the statesman."

After considering the health-laws as they had existed in Rome and in other cities, the author gave some suggestions with regard to how to establish an ideal board of health. The first point which he would make with reference to the organization of local boards

of health was that politics, in the bad American sense, should be utterly excluded. If there was any place where politics had no business, it was emphatically in a board of health. The fitness of the individual, and not his political opinion or his value as a ward-worker, should be the test. It followed from this dogma, which he regarded as fundamental, that boards of health should not be elected by the people,—certainly not in large cities. Boards of health should consist chiefly of physicians. Nor should what was called medical politics—the influence of schools or of cliques and dogmas—be allowed to interfere. The medical members should be graduates of a respectable regular school, of not less than three years' standing in the practice of the profession, and, if possible, they should be chosen from among those who had given attention to sanitary science. It was quite essential, however, that they be not all physicians. At least one member of the board should be a man eminent among his fellows for prudence and judgment in trade and commerce, for doctors were proverbially poor business-men. Emergencies constantly arose in which there was an apparent conflict between the interests of commerce and those of health. It was also desirable that one of the local municipal authorities be on the board. There should also be an agent constantly employed to make investigations regarding the sanitary condition of all localities under supervision of the health board. This person should be a most trusted and respected physician and sanitarian, and he should receive sufficient pay for labor performed. In his ideal board all the members should receive a fair salary.

After a recess, Dr. Samuel N. Nelson, of Cambridge, Massachusetts, read a paper on

MICRO-ORGANISMS AND THEIR RELATION TO DISEASE,

in which he reviewed the labors of German and other bacteriologists in seeking to discover special germs as the cause of various diseases. While we were not yet in a position to express a definite opinion as to the relation of micro-organisms to disease, the author inclined towards the germ theory.

OBSERVATIONS ON THE RELATION OF BACTERIA TO CERTAIN PUERPERAL INFLAMMATIONS.

Dr. Ernest W. Cushing, of Boston, based his observations on the results of examinations of the bodies of such women as had died from these maladies in the general hospital at Vienna last spring. He called attention to the great difference between the rules governing the obstetrician, his assistants and students, in Berlin and in Vienna, saying that in the first-named city every precaution was taken to avoid both direct infection and the possibility of carrying germs in the hair, clothing, etc., as if there might be germs in the air. In Vienna, although the possibility of their existence in the air was admitted in theory, in practice the assistants and students were allowed to be present at autopsies; obstetric operations and laparotomies were performed before classes without spray, and the chief assistant gave an operative course on the cadaver every afternoon, relying for safety on washing, bathing, and change of clothes.

The results obtained by simply avoiding direct infection on the fingers and instruments were used by Dr. Cushing as an argument that puerperal fever was not an entity the poison of which was carried about by the air, entered by windows, was inhaled by the lungs, etc.; but that such fevers were the result of the invasion and multiplication of bacteria received from infection of the uterus or abraded vagina, as a rule, directly from hands, instruments, or applications. From an examination of the bodies mentioned, it would appear that the most frequent cause of infection was the streptococcus; next the staphylococcus; and, lastly, the bacillus pyogenes fœtidus. The former occurred in chains, not distinguishable from those of erysipelas, the cocci lying in pairs, each pair representing a link. The staphylococcus occurred in bunches like those of grapes. One or more of these were found in all acute cases examined, and were present in the uterine or iliac veins, in pelvic abscesses, in the lungs or joints, and, in fact, wherever metastatic abscess occurred.

Dr. Cushing showed microscopical preparations of these different cocci, and gave illustrative cases. He compared puerperal inflammation to infected wounds, and advised active hopefulness with regard to treatment, which, in order to be successful, should be analogous to that of surgical wounds: prompt removal of decomposing matter, evacuation of pus, cleansing and disinfecting douches, and drainage.

This paper was briefly discussed by Dr. R. Stansbury Sutton and Dr. Henry O. Marcy. Dr. Sutton thought the main object was to secure cleanliness. To do this, he would not employ chemical agents in the abdominal cavity, as, by leading to the risk of poisoning, they were more likely to do harm than good; but we could not omit cleanliness. Tait's success was based upon the fact that he secured perfect cleanliness.

Dr. Marcy thought also that Mr. Tait's success depended upon his ability to secure cleanliness, relying largely upon his wife in caring for the sponges, etc.; but he thought Mr. Tait did the cause of surgery harm and himself injustice in depreciating the importance of antiseptic methods. Success was most likely to be with him who took the greatest pains to carry out to the fullest extent antiseptic precautions, while he who spoke disparagingly of these would be least likely to

*

obtain perfect cleanliness, and would meet with failures.

MEDICAL LICENSES AND MEDICAL HONORS.

Dr. Edward Jackson, of Philadelphia, read the paper, and said, "When, one hundred and fourteen years ago, the founders of the University of Pennsylvania and the authorities of King's College, New York, conferred upon six young men the degree of Doctor of Medicine, it meant one thing; when, in this present year, the hundred odd medical colleges of the country conferred upon each of three thousand men and women the degree of Doctor of Medicine, it had come to mean something else.

"So far as State licenses were concerned, they only fixed the minimum amount of knowledge which would be tolerated in a practitioner of medicine: such a license was not honorary. The only good reason for State license was to protect the community from incompetent men. It was doubtful whether any system of State license to pursue a certain calling should be looked upon with much favor; and surely such a license, to be anything but an injury and a hinderance to the advancement of the profession and a delusion and a snare to the laity, should be removed from all possibility of competition, and disinterestedness secured by able and honest examiners and great publicity. The State license should be granted, if at all, directly by State authority. The power should not be delegated to irresponsible competing corporations. Medical honors should be considered of value only when taken in connection with the associations leading to their conferment, or when coming from an institution which had worked its way up to general and popular favor, and which conferred honors only for high professional merit."

A paper entitled "The Physician and his Patient," by Dr. John Devin Kelly, of Utica, New York, and one on "Sketches of Some of the Original Members of the Delaware State Medical Society," by Dr. Lewis P. Bush, of Wilmington, were read by title, which ended the scientific work of the session.

At the close of the business meeting, it was announced that the following officers had been elected for the ensuing year:

President.—Dr. R. Stansbury Sutton, of Pittsburgh.

Vice-Presidents.—Drs. Lewis P. Bush, of Delaware; S. J. Jones, of Illinois; R. L. Sibbet, of Pennsylvania, and F. H. Gerrish, of Maine.

Secretary and Treasurer.—Dr. R. J. Dunglison, of Philadelphia.

Assistant Secretary.—Dr. Charles McIntire, Jr., of Pennsylvania.

Honorary Members.—Drs. Henry H. Smith and S. Weir Mitchell, of Philadelphia.

The next place of meeting will be Pittsburgh, Pennsylvania.

PHILADELPHIA ACADEMY OF SURGERY.

AT a stated meeting held November 2, 1885, D. Hayes Agnew, M.D., President of the Academy, in the chair, Dr. R. J. Levis read a communication entitled

NOTES ON NEW ANTISEPTICS, HYDRONAPHTHOL AND POTASSIO-MERCURIC IODIDE.*

DISCUSSION.

Dr. S. W. Gross: Dr. Levis has made the statement that the potassic mercuric chloride is a far safer germicide than the ordinary mercuric chloride. The solution of one to twelve thousand is really not so much weaker, if we look at it properly. The potassic mercuric chloride is dependent for its activity on the biniodide of mercury. It is a well-established fact that the biniodide of mercury is a far more powerful germicide than is the bichloride. Because we use a weaker solution is no evidence that it is not as strong as the bichloride. I can see no advantage in making the potassic mercuric chloride solution, unless it is to fix the biniodide. In preparing the solution of corrosive sublimate in which we wish to keep gauze, sponges, etc., for a long time, we add to it seven and one-half grains of chemically pure chloride of sodium, with the view of fixing the bichloride so that it will not be converted into calomel. The addition of an equal part of iodide of potassium to the biniodide will fix that salt so that it will not be decomposed. There is therefore really no advantage in it, except to prevent changes in the biniodide.

Hence this is not a new remedy, for the biniodide has been used as a germicide. I do not see any advantage in using a stronger substance in what is apparently a weaker solution. It is, of course, impossible to say anything as regards the constitutional effects, for Dr. Levis has not had sufficient experience to determine whether or not toxic symptoms are produced by this agent. There is no reason why—if the potassic mercuric chloride is used as carelessly as the corrosive sublimate often is—there should not be toxic symptoms produced. If the cases of poisoning with the bichloride of mercury which have been reported are examined, it will be found that the bichloride has been used in unusually large quantities. For example, a one to one-thousand or one to two-thousand solution has constantly been used as a fluid to irrigate the wound during a surgical operation. Again, in psoas and iliac abscess, where a large quantity of the solution has been introduced after the evacuation of the pus, toxic symptoms have arisen. If a little care is exercised, there is no reason why toxic symptoms should arise from any of the mercuric solutions.

In regard to hydronaphthol, I know nothing of it from experience. I, however, know

* See page 126.

that Dr. Fowler has been making experiments with it for years, and, even after the adoption of the mercurial solutions, used saturated compress with naphthaline outside of the corrosive-sublimate dressings to keep the wound enveloped in the vapor of naphthol, according to his statement.

Dr. R. J. Levis: Dr. Gross will bear in mind that with the potassic mercuric chloride there is only one-fifth the amount of mercury used. We know that the mercuric bichloride is an unstable salt in the way in which it is generally used, and for ordinary uses it can hardly be made a stable salt.

Dr. S. W. Gross: It is a stable salt. A solution of corrosive sublimate in water can be kept for a week without any change. To make a stable solution for sponges and dressings, it is better to add chloride of sodium.

Dr. R. J. Levis: I used the term unstable with reference to the mercuric chloride in contact with organic matters. Under such circumstances it is liable to be converted into ordinary calomel.

Dr. S. W. Gross: This is a mistake. Corrosive sublimate does not become unstable in the presence of organic compounds. This has been asserted, but there is no proof of it. If it did undergo this change, why do we have toxic symptoms arising when large quantities of the solution are injected into abscess-cavities?

Dr. J. M. Barton: As regards stability, the mercuric chloride does not seem to undergo any chemical change. At the same time, it undergoes some change when brought in contact with organic matter. If this were not so, a large mass of odorous material could be disinfected with half a grain of corrosive sublimate.

Dr. Charles W. Dulles: It is well known that the salts of mercury in the presence of albumen are apt to be converted into albuminoids, but this does not prevent the constitutional effect of mercury. I believe that this change is not in sufficient quantity to interfere with the antiseptic properties of the substance. The effect of the potassic mercuric chloride in the presence of albumen is somewhat similar. Dr. Oliver, who has made some extensive experiments in regard to albumen in the urine, has found that this potassic mercuric chloride is the most delicate test for albumen.

Dr. S. W. Gross: In corroboration of what Dr. Dulles has said, I would recall the fact that when Lister began the use of corrosive sublimate he employed a solution which was too strong, and found that a certain amount of erythema and vesication was produced. He now procures the serum of the blood of a horse and makes his solution in that way.

Dr. Addinell Hewson: I have had some experience with hydronaphthol, but I have seen it produce irritation, and even such erythema as was alarming. This was a solution of one to two thousand. The effects were produced within twenty-four hours. The patient experienced constant distress from the time of its application.

Dr. R. J. Levis: I have found the one to two-thousand solution almost tasteless. I have placed it in one eye without being conscious of its presence.

Dr. Addinell Hewson: In this case there was a tendency to erythema, and the result undoubtedly proved that the remedy had no effect as a germicide.

Dr. Levis: That is not claimed for it.

Dr. F. H. Gross reported a case of laparotomy.*

A SUTURE FOR THE APPROXIMATION OF DEEP WOUNDS.

Dr. R. J. Levis: I wish to call attention to a suture to be used in place of the buried suture. Every surgeon recognizes the advantages of approximating the surfaces of wounds as conducing to healing. We have all been too much satisfied with approximating simply the edges of wounds, without paying attention to the approximation of the deeper parts. In amputations and in the removal of tumors from such situations as the groin and axilla, large spaces are left which may become filled with blood, serum, or the products of inflammation. Since the introduction of antiseptic surgery, and particularly since the use of animal sutures has been adopted, some surgeons have used what are called buried sutures. These have their disadvantages, and sometimes it is difficult to apply these sutures so as to secure complete approximation.

Some time ago I devised a simple plan of approximating the deeper parts of a wound. Taking an amputation-wound for illustration, to approximate the flaps in this manner I take an ordinary silver wire armed at each end with a straight needle, introduce one of the needles into one flap at the bottom of the wound, and bring it out about half-way between the angle of the wound and the edge of the flap. It is then carried across the wound and through the opposite flap. The second needle is then carried through in the same manner. A figure of 8 is thus formed. When the ends of the wire are drawn upon, the deeper portion of the wound is approximated. The superficial portions of the wire are then carried across the wound and bring the edges together. Superficial sutures are also introduced. I have used this in a number of amputations, and think it particularly applicable to the closure of wounds after the removal of large tumors of the breasts where the axillary glands are also removed. In a case in which I removed the breasts four days ago there is now complete union. I insert as many of these sutures as may be necessary.

* Will appear in the next issue of the *Times*.

I have always used wire, but ligature rendered antiseptic would probably be almost as good.

Dr. J. Ewing Mears: In deep wounds of the axilla, what tissues do you approximate?

Dr. Levis: Fatty tissue, muscular tissue, or whatever may be necessary.

Dr. Addinell Hewson: I have used the suture of Dr. Levis frequently, but I have used it without the addition of superficial sutures. I employ, instead, collodion and gauze. This I find more satisfactory. I have had direct union through a stump without any suppuration whatever, on more occasions than one.

Dr. S. W. Gross: I have seen Dr. Levis apply this suture, and it does approximate wounds in a most excellent manner. It is very easy to get the suture out. It is very desirable to get rid of the presence of any foreign body in the wound. Neuber, the introducer of the decalcified-bone tubes, recognized their inconvenience, as well as the disadvantages of the ordinary rubber drainage-tube. It was he who proposed buried sutures. He also resorted to other means of drainage. In amputation of the breast he occasionally punched holes in the skin to allow free drainage. In removal of axillary tumors he inverted the skin on each side, attaching the anterior portion to the pectoralis major and the posterior to the latissimus dorsi, thus making a funnel-shaped opening through which drainage could be effected.

Dr. T. G. Morton: During last winter, something similar to this was proposed by Dr. Packard at the Pennsylvania Hospital. He suggested the introduction of a long pin across the stump, and then the application of a figure of 8 around, making careful compression. This would answer very much the same purpose.

Dr. R. J. Levis: This suture might be called the duplex suture or the deep crossed suture. I think it would be very suitable in the high operation for stone, the deep portion of the suture including the bladder and the superficial portion, including the superficial tissues.

PIN FOR TREATMENT OF FRACTURE OF THE PATELLA.

Dr. Morton: I wish to exhibit a pin which I have used in the treatment of fractured patella. For a number of years I have been using the ordinary Malgaigne's hooks and the modified Malgaigne's hooks. It occurred to me that if I could pass a steel pin and keep the fragments approximated I should have an easier method than with the hooks. I devised this pin, which has a detachable handle and works as an ordinary Brainard's drill. In the case in which I applied it the pin went through without difficulty. Over the extremities shoulders were applied. The fragments were then not disturbed for three weeks. There was not the slightest irritation. Lead-water and laudanum were kept applied. When the pin was removed, I found under one of the shoulders a small collection of pus. In order to obviate this, I have had a shoulder made which does not come in contact with the skin at a right angle. To avoid the possibility of pulling any pus into the bone when removing the pin, I have made it in two pieces, united in the middle with a screw. When it is desired to remove the pin, the parts are unscrewed and the two pieces removed. I have had less trouble with this than with any other method of treating fractured patella.

In introducing the pin I did not employ any anæsthetic, and the patient made no complaint. The whole manipulation did not occupy over fifteen seconds. It is impossible to apply Malgaigne's hooks without an anæsthetic. I was surprised at the ease with which the pin passed through the bone. It met with no more resistance than it would in going through a hard Boston cracker.

I was unable to apply the pin until thirteen days after the fracture, on account of the effusion within the joint. I have never put on the hooks until all local irritation has subsided.

In this case I do not think that there is bony union. I have never seen bony union where there has necessarily been delay, but there is here exceedingly close union.

Dr. William W. Keen reported a case of

OBSTRUCTIVE JAUNDICE—CHOLECYSTOTOMY FOR IMPACTED GALL-STONES.*

DISCUSSION.

Dr. William Hunt: What has been the success following this operation?

Dr. Keen: I have not had time to gather the cases together; but when I prepared my paper last year there were thirty-eight cases, with eight deaths.

Dr. S. W. Gross: The percentage of deaths after cholecystotomy is eighteen. The percentage of deaths is far greater than after removal of the gall-bladder, or cholecystectomy.

Dr. J. Ewing Mears: This case serves to confirm what every one who has had anything to do with abdominal surgery believes,—that it is frequently impossible to tell what will be found in the abdomen before it is opened. This case was carefully examined before operation, and what was supposed to be the gall-bladder was outlined; but, when the abdomen was opened, this proved to be the left lobe of the liver. This may be regarded as one of the most obscure cases of cholecystotomy that has yet been performed. In the reported cases there has been no difficulty in locating the position of the gall-bladder.

Dr. W. W. Keen: In the three prior operations which I had done, there was no difficulty in finding the gall-bladder.

DEFORMITY OF THE UPPER EXTREMITIES.

Dr. W. W. Keen: I have here a patient with a deformity of the upper extremities,

* See page 123.

which I suppose is due to rickets. Precisely similar conditions I have never before seen. This girl is in her fifteenth year, a mulatto, tall and rather slender for her years. One year ago she began menstruating, and at the same time noticed the commencement of the changes which are now most distinct in the right wrist. There is also marked angular deformity at the elbow. Feeling the olecranon process, there is found considerable relaxation of the ligaments, allowing the ulna to be moved in different directions. In the wrist there is apparently no mechanism which would account for the deformity present. The deformity of the left wrist can, with the exercise of considerable force, be reduced. I would call attention to the ease with which the deformity of the elbow would be overlooked. When the hands are pronated it is not seen: it is observed only in supination. The other bones of the body are free from evidences of rachitis. There is no trouble about the head, no beading of the ribs or enlargement at the ankles. There is no evidence of inherited specific disease: the father died of consumption, the mother is living and perfectly healthy. There is no evidence of specific disease to be found in the condition of the teeth.

Dr. Charles W. Dulles: Would this not be more properly called a case of osteomalacia? Rickets is an affection of the bones in the progress of their growth. Osteomalacia is the term applied to the condition in which bones, having attained their proper development, undergo softening.

Dr. Keen: The bones are not curved to any extent, and in no other bone is there a tendency to softening.

Dr. R. J. Levis: My opinion is that the case is really a neurosis. I look on it as a paralytic condition rather than a true bone-affection. It is analogous to some forms of club-foot, and particularly to knock-knee and the like, which, we know, occur from irregular muscular action.

Dr. W. W. Keen: I cannot understand how this condition could be due to muscular action, either paralysis or contracture. There is no evidence of such a condition. No muscle is tight, and no muscle springs into relief at any point. The muscles seem to act properly, and the trouble appears to be in the bony system. In consequence of the change in obliquity, the muscles which go across as chords of the arc tend to increase the deformity.

My attention has been drawn to the diminished size of the head of the radius. This might have something to do with the deformity at the elbow, but it could have nothing to do with the condition of the wrist.

Dr. William Pancoast: I noticed that, on pressing the radius firmly against the ulna, a grating could be produced. This was elicited only on firm pressure.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, OCTOBER 1, 1885.

The President, B. F. BAER, M.D., in the chair.

DR. WHARTON SINKLER read a paper on

THE DIFFERENT FORMS OF PARALYSIS MET WITH IN YOUNG CHILDREN.

The most frequently met form is infantile paralysis, or *polio-myelitis anterior*. This term indicates the pathology of the disease, which is an inflammation of the nerve-cells of the anterior horns of white matter of the spinal cord. This affection may come on at any period of life, but is generally seen in children, and usually at the age of two years. The children are generally strong, and apparently healthy, and the paralysis is sudden in its onset. Fully two-thirds of the cases I have seen have been attacked in the summer months, hot weather and teething seeming to be predisposing agents. Dr. Barton, of Manchester, England, reports that of fifty-three cases in which he noted the time of onset, twenty-seven occurred in July and August. The attack is preceded by fever of greater or less intensity, with pain in the head and limbs, with general soreness when moved or lifted. After a few days, paralysis, more or less complete, occurs; but subsequently a regression of the paralysis from some of the affected parts occurs. Sensation is undisturbed. Atrophy of the muscles is soon apparent; in fact, the paralyzed portion stops growing for a time. The temperature of the affected portion is low, and the skin is blue and mottled, but there is no tendency to ulceration, and wounds or scratches heal readily. The skin and tendon reflexes are lowered or abolished in the affected limbs. At first response to the faradic current is lost, and later on the galvanic current produces but little muscular contraction, except when a powerful current is used. When atrophy has set in, the reaction of degeneration is seen. Most of the cases of club-foot are the result of infantile palsy. Deformities of the upper extremities are rare, this disease differing in this respect from cerebral palsies. The exact causes of infantile palsy are unknown. Over-fatigue often precedes an attack; sudden chilling is considered by Seguin to be a frequent cause.

The *prognosis* as to perfect recovery is only moderately good. In many cases the most faithful treatment fails to restore the paralyzed muscles, but in almost every case we can expect more or less improvement.

In the early stages of the paralysis, after the subsidence of the fever, the treatment should consist of mild stimulation to the spine; ergot and small doses of bromide of potassium should be given internally. Later in the disease, iodide of potassium should be given instead

of the bromide. When the palsy is established, electricity and massage are the means to be depended upon. They must be persisted in for months, or even for years. Internal treatment is of little or no value unless there is some failure in the general health of the child.

Spasmodic paralysis, as seen in children, is of two varieties: when of primary spinal origin, and when there is a descending degeneration of the cord from a primary cerebral lesion. Sometimes there seems to be a congenital defect in the motor tracts of both brain and cord. In the spinal variety there is often seen, soon after birth, rigidity of the limbs. At first this is only occasional, but as the child gets older every effort to move a limb causes muscular rigidity in it. The child does not attempt to walk until three or four years of age. Then, when it is supported under the arms, and it tries to stand or to walk, the movements are very peculiar and characteristic. The feet are extended and inverted, so that the child rests on the toes. The knees are strongly adducted and lock together, so that the legs become entangled. By degrees the child becomes able to walk with the aid of apparatus or some form of crutch. The hands and arms are often affected, and every effort causes muscular rigidity to come on. The mind is unaffected in these cases, and the speech may be distinct, although it is often very defective. Sensation is unimpaired, and the patella reflex and ankle clonus are exaggerated. There is no wasting of the muscles. By these symptoms we infer that the disease is localized in the lateral columns; but exactly what is the nature of the lesion we do not know, for no post-mortem examinations have been made in these cases. The cause is unknown. Hamilton found three of seven cases which he had collected were premature births. Adherent and contracted prepuce has been thought by some to be caused by reflex influence of the spasmodic paralysis, but operation has not given relief. The treatment should consist of massage, galvanism to the spine, ergot, and cod-liver oil. Fluid extract of conium may be given to allay spasm. In some cases great improvement follows this treatment. Even when we can do no positive good to the limbs, very much can be effected by the aid of apparatus. Properly-adjusted braces to the legs will enable a child to walk on crutches or in a Darrach wheel-crutch.

There is a form of spasmodic spinal paralysis in which the child is imbecile. In these cases there has probably been congenital defect in cerebral development. The head is small, and there is no evidence of intellect; often nystagmus is present.

Paralysis from Pott's Disease.—Paralysis of the lower extremities may result from caries of the spine. The lesion may be either a meningitis or a myelitis. If meningitis alone, there is considerable pain and contraction of the legs. Generally there is a transverse myelitis. The symptoms are numbness and pricking of the legs, with loss of sensation; gradually-increasing loss of power, with wasting of the muscles; incontinence of fæces, with retention or incontinence of urine. Sometimes there are ulcers over the sacrum or on the limbs.

The indications for treatment are evident. An apparatus which will take the weight of the body from the spine is necessary, and is sometimes sufficient of itself. Frequently, however, the application of the actual cautery over the spine brings improvement in the symptoms when an apparatus has done no good. Massage and electricity should be used to restore the atrophied muscles.

Paralysis from rachitis and diphtheria is seldom complete. The former is often spoken of as the pseudo-palsy of rickets. Negro children, who are very subject to rachitis in cities, often have rachitic paralysis. The child at three or four years is unable to walk or stand. Sometimes it has not sufficient muscular development to sit upright. It can move every limb, and has no loss of sensation, but has no power. Cod-liver oil and massage bring about the most satisfactory results in these cases. *Diphtheritic paralysis* usually begins in the muscles of the soft palate and pharynx, and extends to the extremities. It is generally bilateral and incomplete, but I have seen a case in which it was hemiplegic. It is considered peripheral in character, and is believed by some to be connected with the altered condition of the blood consequent on the original attack. Diphtheritic paralysis is rarely fatal, and lasts in most cases only a few weeks, although it may continue for months. Strychnine and electricity are the means to be employed, and the case usually responds promptly to these remedies.

Pseudo-hypertrophic paralysis is a rare affection, but is of much interest. The disease belongs almost exclusively to infancy. It is characterized by muscular paralysis, with great increase in the bulk of the muscles. This enlargement is due to fatty deposit, while the muscular tissue proper is atrophied. The affection begins with weakness of the legs, a peculiar balancing of the trunk, and separation of the legs in walking. The shoulders are thrown far back in standing and walking. There is great difficulty in getting from the sitting to a standing position. Later in the disease the muscles become wasted and shrunken, and the general health begins to suffer. Death results from implication of the respiratory muscles. The skin is mottled like a piece of Castile soap. The tendon reflexes are abolished, and electro-muscular contractility is impaired. There is often a greater or less amount of mental weakness. There is no loss of power over the bladder and rectum, and sensation is not affected. Heredity in-

fluences the disease, which is slow in its progress, but the course is steadily downward.

Friedreich's disease is still more rare than the preceding. It is practically locomotor ataxia in childhood. There is evidenced here also a hereditary predisposition, and female children seem most liable.

Cerebral Palsies.—Hemiplegia may result from some injury at the time of birth, either from the forceps or from the pressure of a prolonged labor. A child may be born hemiplegic after a perfectly natural and easy labor. Under these circumstances we must regard the paralysis as the result of imperfect cerebral development. Hemiplegia under these circumstances is generally permanent. The side affected grows less rapidly than the other. The flexors of the arm and hand are usually contracted. The leg becomes rigid in the act of walking.

Convulsion is almost always associated with cerebral paralysis, either immediately preceding the attack or occurring soon after. The convulsive movements are most violent on the side which is subsequently paralyzed. The child will have an idiotic expression and speak indistinctly, but its friends think it intelligent. The convulsions are liable to return when the child is older, and then assume an epileptic form. The walk is peculiar, and is called the *spastic* gait. The patient plods along looking as if he were about to pitch forward. The affected limbs are smaller and shorter, the growth of both bone and muscle being affected. In the choreic variety, where the arm is in constant motion, the muscles may become hypertrophied, but the bone remains short.

Prognosis.—As a rule, the prospect of recovery is bad: even if the patient gets well, the hemiplegic side remains awkward.

Treatment.—Cod-liver oil and massage, which always relaxes the contracted muscles. The affected limbs should be used as much as possible.*

Dr. HARRIS inquired if Dr. Sinkler had ever observed any hereditary predisposition to convulsions and cerebral paralysis.

Dr. SINKLER replied that the hereditary influence was decided even when no convulsions occurred.

CÆSAREAN SECTION.

Dr. R. P. HARRIS read a report of the autopsy upon Mrs. R., from whom two living children had been removed by Cæsarean section by Professor Gibson, of the University of Pennsylvania. The superior strait was reniform; conjugate diameter one and three-quarter inches, transverse diameter five and one-quarter inches. The malformation was due to rachitis and injury from a fall in her second year. A full report of the history of the patient, the operations, and the autopsy, can be found in the *American Journal of the Medical Sciences*, October, 1855, p. 422.

* The paper, with illustrative cases and details of treatment, will be published in full in the *Archives of Pediatrics*.

OÖPHORECTOMY.

Dr. E. E. MONTGOMERY reported the following case. Mrs. L., of Columbia, Pennsylvania, æt. 36 years, married ten years, pregnant five times, the last four years ago, was brought to my notice by Dr. H. T. Chase. Her health has been bad since her last confinement. First menstruation at twelve and a half years, regular and very free for one and a half years, when she fell, producing pelvic distress, after which for seven years the flow was very scanty, lasting but one or two days, and accompanied by excruciating pain. She improved somewhat after marriage. Her first conception was followed by so much nausea, vomiting, and anæmia that her physician advised and induced an abortion.

She is now regular as to time, but irregular as to quantity. It is preceded by an excruciating pain for two days, which continues until the flow disappears. She also has severe pain in the head. She is very nervous at all times, but this is much intensified during the period. Pain is more marked in the left inguinal region and down the corresponding limb. Coition and vaginal examination are very painful. The uterus is enlarged and painful, tender on pressure over both ovaries. Local uterine treatment had been kept up during the entire four years with no relief. Trachelorrhaphy had been performed; ovariotomy was advised. September 19, 1885, she entered my private hospital, and, assisted by Drs. W. H. and C. B. Warder and E. Eshleman, the uterine appendages were removed. The left ovary was composed of a number of cysts, the largest of which ruptured while adhesions were being separated. The right ovary was not enlarged, but it was removed to insure relief. The wound was closed with silk-gut, and dressed with sublimated gauze and absorbent cotton. There was no shock. The highest temperature reached was 101.6° at midnight of the 20th, and it became normal on the 22d. Sutures were removed on the eighth day, and the wound re-dressed for the first time. It had united throughout, and there was no irritation from the sutures. The effect upon her general health remains to be determined.

Dr. MONTGOMERY also reported a case of

SUPRA-VAGINAL REMOVAL OF THE UTERUS AND BOTH OVARIES FOR FIBROID TUMOR.

Ann U., æt. 27, was brought to me by Dr. T. H. Boysen, of Egg Harbor City, with the following history. Her menses from the beginning occurred every three weeks, and were free an entire week. During the last four years they have occurred every two weeks, and are attended with pain in the pelvis and down the limbs, and severe pressure upon the

bladder, causing frequent urination, and several times necessitating the use of the catheter. Dr. Boysen had diagnosticated fibroid tumor, which my subsequent examination confirmed. The tumor was the size of a child's head, filling up the pelvis, and apparently arising from the anterior wall. The examination led me to believe that the bladder was adherent over the anterior surface, and would render the removal of the tumor unsafe. I suggested the removal of the ovaries. She entered my private hospital September 15, 1885, for that purpose. Drs. W. H. Warder, Boysen, and Martin assisted; Drs. C. B. Warder and Stultweather present. An incision three inches long was made, and finding the tumor free from the bladder, with cervix sufficiently long to serve for a pedicle, the incision was extended to within an inch of the umbilicus above and symphysis below, and the tumor with some difficulty withdrawn. In the absence of a Tait's clamp, which had been ordered some days before, the pedicle was constricted by a wire écraseur, and the tumor, with the ovaries, was removed. The pedicle was then transfixed with two steel pins, and tied in three sections with strong silk thread. The peritoneum was fastened to the pedicle below the ligatures, and the wound closed with silk-gut sutures, the pins holding the stump outside. The wound was dressed with sublimated gauze and absorbent cotton. The operation was followed by some shock,—temperature 97.4°, pulse 104,—from which she soon rallied. She complained greatly of pain. A half-grain of morphine had been given by suppository, and three hypodermic injections of morphia, one-quarter grain each, were given during the afternoon before the pain was relieved.

At 3 A.M. of the 24th I was called by the nurse, who reported bleeding from the stump. Three ounces of blood had been lost. By aid of Dr. Warder a Wells's clamp was applied below the pins, apparently controlling the hemorrhage; but it recurred later in the day from the angles and from beneath the clamp. By this time the Tait's clamp had arrived, and the patient was etherized, the lower three sutures removed, the pedicle drawn up, the clamp applied so as to control it completely, and the wound again closed. The wound had united throughout. Temperature reached 100.6° at 9.30 P.M. The highest subsequently, 101.6°, was in the afternoon of the 25th, and it became normal on the 28th. Upon removing the dressings on the 27th, some pus welled up about the pedicle. As the skin was irritated, the dead pedicle was cut away until the clamp slipped off. There resulted, of course, considerable retraction of the stump, but the sloughed tissue is now nearly cleared away. The patient suffers no pain or discomfort; temperature normal. The tumor was situated in the anterior wall and fundus uteri, and projected into the uterine cavity.

Dr. PARISH remarked that removal of the ovaries had given such good results in cases of uterine fibroids, and was comparatively so free from danger, that he would like to hear from Dr. Montgomery his reason for his choice of operation.

Dr. MONTGOMERY replied that the tumor filled the pelvis and pressed upon the bladder and rectum, causing great and constant distress. As diminution of the size of the fibroid tumor is not a certain result of oöphorectomy, and as all the circumstances were in favor of the major operation, he decided upon it as the best one.

W. H. H. GITHENS,
Secretary.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held October 28, 1885, the President, JOHN A. WYETH, M.D., in the chair.

The Committee on Microscopy reported on the specimen of exfoliative catarrh of the bladder presented by Dr. Boldt at the last meeting. So far as could be determined with the specimen in its present condition, it could not be regarded as a cast of the urinary bladder in the sense it was supposed to be by Dr. Boldt: it only contained a part of the superficial layer, and its thickness was due to new deposit with œdematous infiltration.

Dr. W. M. CARPENTER presented two specimens for candidates. The first was a primary ulcer of the duodenum, situated within half an inch of the pyloric orifice, one and one-half inches by one inch in size; there was no perforation of the intestine, but peritoneal adhesions surrounded the ulcer.

CARCINOMATOUS ENLARGEMENT OF THE LIVER AND CANCEROUS DEPOSITS IN VARIOUS ORGANS OF THE BODY OF A GIRL AGED THIRTEEN YEARS.

The second specimen consisted of the greatly-enlarged liver from cancerous nodules, and was removed from the body of a girl aged 13 years and 6 months. There were also nodules in almost all of the organs of the body where such deposits usually occurred. Her father had died of phthisis; two cousins of her grandfather were believed to have had cancer of the breast. The child had always been considered very healthy. A year ago she was in vigorous health, and weighed eighty pounds. About the middle of August last she began to complain of feeling tired, lost color, and became listless. At first she had no pain, but later would cry out with pain in the region of the spleen. Her appetite became ravenous, and she ate with special pleasure things acid. Enlargement of the abdomen was first noticed on the 8th of September, and from that time there was rapid increase in the region of the liver. Death

occurred in October. The liver weighed twenty pounds, and contained cancerous nodules of various sizes: the lungs were about the only organs free from cancerous infiltration.

The specimen was referred to the Microscopical Committee for examination.

Dr. LOUIS WALDSTEIN also presented a specimen for a candidate, consisting of the first phalanx of the great toe, the seat of a semi-malignant tumor following an injury. The disease showed some signs of becoming actively malignant.

FIBRO-MYOMA OF THE UTERUS.

Dr. H. MARION SIMS presented a round tumor of the uterus the size of a child's head. The patient had been married eighteen years, had had one child some years ago, had menstruated regularly and had been in remarkably good health until three years ago, at which time she began to suffer from heavy, dragging pains, and also from darting pains in the iliac regions. She consulted him in October, when the uterus was four inches in depth; a movable tumor was felt, which was believed to be a uterine fibroid. The patient was very fat, and the abdominal incision had to be increased to nine inches in order to extract the growth. The patient rallied well from the operation, and did well, but on the third day complained of oppression about the stomach and vomited a quantity of black fluid, evidently from reverse peristaltic action in the intestines. It would seem that some of this material entered the air-passages and the patient died suddenly from suffocation.

The autopsical examination was limited to the abdominal cavity; the wound was in good condition; there were no signs of suppuration.

Dr. Sims also exhibited two vulcanized plates with grooves upon which the skewers could rest and not cut into the abdominal integument.

Dr. J. B. HUNTER had had like trouble with the skewers, for the prevention of which he had had flat buttons put on the ends of the skewers; but the plates shown were preferable, being larger. R. C. S.

PILOCARPINE IN ERYSIPELAS.—The treatment of erysipelas introduced by Prof. Da Costa, by the administration of jaborandi or pilocarpine, has been employed by others with similarly successful results. Dr. Charles W. Rook, of Quincy, Illinois (in a contribution to the *Medical and Surgical Reporter*), reports two cases of facial erysipelas treated with fluid extract of jaborandi (gtt. xxx every half-hour for five hours), followed by tonic doses of iron and quinine. In one case vomiting was produced, which was attributed to swallowing the salivary secretion.

REVIEWS AND BOOK NOTICES.

MOISTURE AND DRYNESS; OR, THE ANALYSIS OF ATMOSPHERIC HUMIDITIES IN THE UNITED STATES. An Essay read before the American Climatological Association (1884), and including the Presentation of a Rule of Moisture and Dryness by which the Climate is evenly divided, etc. By CHARLES DENISON, A.M., M.D. Chicago. 1885. 8vo, pp. 30.

The value of Colorado as a sanitarium is demonstrated by this study of comparative humidity of the air in different portions of the United States, which is accompanied by weather-maps prepared by the Signal Service of the War Department. The essay is based upon the proposition that "an actually small amount of atmospheric moisture is the most important element in the best climate for phthisis." Equability, so long the desideratum, is shown to be illusory and injurious, and the author contends with much vigor for coldness, variability, and stimulation, as against their opposites, warmth, equability, and enervation. The influence of various factors in producing atmospheric dryness or the reverse is considered, and localities similar in other respects are shown to be favorable to the invalid in proportion to their dryness; and, as cold favors the elimination of carbonic acid, the conclusion is reached that altitude and distance from the sea are of great value in a health-resort for consumptives.

RATIONALISM IN MEDICAL TREATMENT; OR, THE RESTORATION OF CHEMISM. BY WILLIAM THORNTON. Boston, published by the Author. 1885.

This brochure is dedicated appropriately to those who think and reason. Restored chemism, in the language of the author, "means the re-establishment of the normal relative position of the atom, which brings about the chemical and physical integrity of the body, as the human system can be made to respond to chemical action, if understood, as easily as the crank of an instrument responds to the touch of the musician." If, as he asserts, rationalism in medicine requires the throwing aside of two-thirds of our materia medica, we hail its champion, and hope that he will not set his lance at rest until he has demolished every therapeutic windmill.

A TEXT-BOOK OF NURSING. For the Use of Training-Schools, Families, and Private Students. Compiled by CLARA S. WEEKS, Superintendent of Training-School for Nurses, Paterson, New Jersey, etc. New York, D. Appleton & Co. Cloth, 12mo, pp. 396.

This book, in twenty-three chapters, communicates a large quantity of useful information in a form intelligible to the public. It is

well written, remarkably correct, sufficiently illustrated, and handsomely printed. The amount of technical skill and knowledge required of nurses at the present day makes the use of some text-book indispensable. To those who need such a work we can speak approvingly of its design, scope, and execution.

THE PEDIGREE OF DISEASE. Being Six Lectures on Temperament, Idiosyncrasy, and Diathesis, delivered in the Theatre of the Royal College of Surgeons at the Session of 1881. By JONATHAN HUTCHINSON, F.R.S. New York, William Wood & Co. 1885. Cloth, 8vo, pp. 113.

These lectures have already appeared in the medical journals, but the profession will welcome them in this permanent and more acceptable form.

NEW REMEDIES AND CLINICAL NOTES.

THE SURGICAL TREATMENT OF CYSTS OF THE PANCREAS.—Of all abdominal organs, the pancreas has been least frequently subjected to surgical treatment, for which the anatomical location of this organ and the obscurity of its affections furnish a sufficiently satisfactory explanation. Situated high up in the abdominal cavity, and hidden behind such important organs as the stomach, omentum, and transverse colon, it is the least accessible of all the abdominal organs, and on this account its affections, wrapped in obscurity, have for the most part constituted objects for empirical medication. The relation of this gland to the surrounding organs, and its great distance from the anterior wall of the abdomen, the only point of approach, necessarily offer serious obstacles to diagnosis and direct treatment. From a diagnostic point of view, another great difficulty is our want of positive knowledge concerning the physiological functions performed by this gland in the process of digestion. As the symptomatology of all affections of the pancreas is always obscure, and a probable diagnosis can be made only in cases where the gland has become considerably enlarged by disease, it is apparent that our present clinical knowledge is limited to diseases which increase the size of the organ to a sufficient extent to permit its detection by palpation. Primary malignant disease of the pancreas, when it has advanced to such an extent that its presence can be diagnosticated with certainty by physical signs, will have invaded the adjacent tissues to such a degree as to preclude the advisability of an operation. Consequently, the efforts of the surgeon, for the present at least, must be directed exclusively towards the recognition and treatment of benign affections of this gland. Clinical experience does not extend beyond an imperfect knowledge of cysts of the pancreas.

The pancreas, like other secretory organs, is prone to become the seat of cystic tumors, the result of obliteration or obstruction of the common duct or one or more of its branches. Cysts originating in this manner are true retention-cysts, containing the physiological secretion from the distal portion of the gland-tissue, with perhaps accidental products, such as altered secretions, blood, and the products of inflammation.

In a very valuable paper on the surgical treatment of cysts of the pancreas, Dr. N. Senn, of Milwaukee, in the July number of the *American Journal of the Medical Sciences*, presented a full report of a case of retention-cyst of the pancreas which had recently come under his observation, and at the same time summarized in a compact form the clinical history of similar recorded cases, which serve as a basis for some general remarks.

In recapitulation, Dr. Senn submits the following conclusions:

1. Cysts of the pancreas are true retention-cysts.

2. Cicatricial contraction or obliteration of the common duct or its branches, and impacted calculi, are the most frequent causes of cysts of the pancreas.

3. A positive diagnosis of a cyst of the pancreas is impossible; a probable diagnosis between it and some other kind of cyst amenable to the same surgical treatment is adequate for all practical purposes.

4. The formation of a pancreatic fistula under antiseptic precautions commends itself as the safest and most expedient operation in the treatment of cysts of the pancreas.

INOCULATION FOR HYDROPHOBIA. — M. Pasteur has communicated to the Academy of Medicine and the Academy of Sciences the results of his latest experiments upon the prophylaxis and cure of rabies, together with the account of a case observed in the human subject. M. Pasteur now adopts the following method: A rabbit is inoculated with a fragment of the spinal cord of a mad dog; the animal is affected with hydrophobia in the space of about one fortnight. A portion of its spinal cord is employed to inoculate a second rabbit, which also contracts the disease, but more rapidly; the spinal cord of this second rabbit serves to inoculate a third, and so on. It is observed that at each step of this process the intensity of the disease becomes greater and the period of incubation shorter. When the spinal cord of these animals which have died of hydrophobia is suspended in a perfectly dry tube, its virulence diminishes by degrees, and at last disappears. A collection of these spinal cords —some of them entirely stale and powerless, others more fresh and active, others again

quite fresh and extremely active—is always kept in readiness. To render a dog insusceptible of rabies, he is first inoculated with the stale and powerless specimens, then with fresher and more active ones, and lastly with the most powerful of all, when he becomes quite proof against the inoculation of rabies. Lately, a young boy, 9 years of age, Joseph Meister, was brought by his friends to M. Pasteur's laboratory. He had been most severely lacerated by a mad dog, having fourteen bites in different parts of his body. M. Pasteur, in presence of the almost absolute certainty of death, inoculated the child according to his system: the first inoculation was made with a spinal cord fifteen days old on the 6th of July, sixty hours after the child had been bitten. Similar inoculations with virus of constantly increasing intensity were made up to the 16th of July, when the spinal cord employed was quite fresh. The child, having up to the present time, four months after the accident, exhibited no symptoms of hydrophobia, is considered radically cured by M. Pasteur, and he has already recommenced the same method of treatment upon a young shepherd, who, in defending other boys, was cruelly bitten by a mad dog, which he killed upon the spot. The results of this new experiment will be communicated by M. Pasteur in due time to the Academy. With respect to the first patient, it must be remembered: 1. That sixty per cent. of people bitten by mad dogs do not contract hydrophobia. 2. That the incubation of the disease is sometimes extremely long (cases have been known to occur two years after the bite). The experiment is not, therefore, absolutely conclusive, although it marks a great progress in the history of the disease, and justifies in some measure the enthusiastic applause with which the communication was received.—*Medical Times and Gazette.*

PILOCARPINE THE ANTIDOTE TO DATURINE.—A Hungarian physician, being called to a child of four who was in a comatose condition from having eaten, as her playfellows said, two handfuls of the ripe berries of the thorn-apple (*Datura Stramonium*), and in whose vomit the berries could be plainly detected, gave pilocarpine hypodermically, thinking that, as that had proved successful in atropine-poisoning, it ought to be useful in datura-poisoning also. He began with the fourteenth of a grain, and, as no effect was produced, he increased the dose to a seventh. As improvement was now evident, this was repeated. Altogether in five hours he gave six-sevenths of a grain, and by that time the child was convalescent. No physiological symptoms of pilocarpine were produced until the last dose was given, which was followed by profuse secretion of saliva and perspiration. The author therefore concludes that five-sevenths of a grain of pilocarpine had been required to neutralize the daturine, its own physiological action not coming into play until that was completely effected. He thinks that this case sufficiently demonstrates that pilocarpine is antidotal to daturine.—*Medical Times and Gazette.*

A NEW CANCER-CURE.—The *Euphorbia heterodoxa*, a native of Brazil, possesses a resinous active principle, contained chiefly in the juice, which exerts a peculiar destructive action upon certain neoplasms. Dr. Landowski, at the recent French Congress at Grenoble, called attention to the fact that the juice of this plant had the reputation among the natives of curing cancer. He had experimented with it in chancroids, epitheliomata, syphilitic vegetations, and had found it to possess a powerful escharotic effect, with a dissolving action upon organic tissues, resembling a combination of a powerful caustic with papaine. The remedy is applied with a brush, and the tumor dressed with vaseline containing boric acid. Dr. M. de Santa Cruz has found that the resin possesses the same properties as the juice, and is permanent, while the juice quickly deteriorates.

IN trigeminal neuralgia, two-thirds of a grain of salicylate of cocaine, injected into the most painful spot and repeated several times, has been found curative by Dr. M. Schneider.

ANTIPYRIN may be given in syrup of raspberries, syrup of lemon, simple elixir, compound elixir of taraxacum.

MISCELLANY.

AT the stated meeting of the Medical Jurisprudence Society held on the 10th instant, at the Hall of the College of Physicians, Dr. John H. Packard and Thomas W. Barlow, Esq., jointly presented a paper on "The Extension of Privilege to Communications between Physician and Patient." Several new members were received.

NOTES AND QUERIES.

THE EXTERNAL APPLICATION OF THE TINCTURE OF BELLADONNA IN RETENTION OF URINE.

TO THE EDITOR OF THE PHILA. MEDICAL TIMES:

A short time ago I was hurriedly summoned to see a little boy who was suffering much from retention of urine, brought about by a kick, by another boy, received on the perineum just over the prostatic portion of the urethra, producing not only paralysis of the muscles of that part, but also enlargement of the prostate gland, with stricture and retention of urine, and all efforts at urination were futile. For three days this state of affairs

had continued without any relief, but all the while getting worse, notwithstanding all the efforts which had been made to relieve him. The case was now one of critical importance, as life depended upon a speedy relief. I at once ordered a warm hip-bath for ten minutes, hoping at the end of it to be able to pass a small-sized catheter, but signally failed. Then I applied the tincture of belladonna over the *lower part* of the abdomen and perineum, hoping to relax the muscular contraction. At the end of another ten minutes I made a second attempt to pass the catheter, which I succeeded in doing, as there flowed a few drops of bloody urine. Feeling satisfied at the success, and knowing that I had broken the way and relieved the stricture, I desisted from the further use of the instrument, fearing that I might do some harm and thereby increase the trouble. I ordered the patient to be wrapped in warm blankets and put to bed, giving him one grain of opium and a half-grain pulv. ipecac every hour until he slept soundly, occasionally bathing the perineum with the tincture of belladonna. He fell into pleasant sleep, and at the end of five hours awakened and passed one quart of urine, and that without trouble. The relief was permanent. The treatment was continued for a few days, and the patient was well. As an evidence of the fact, he has been playing around the streets every day since. J. A. H.

Milton, Del., October 31, 1885.

COCA-LEAF CHEROOTS.

To the Editor of the Phila. Medical Times:

Dear Sir,—I have received such a flood of letters in relation to coca-leaf cigars and cigarettes from all parts of the United States, since my article on this subject in your issue of October 19, that I feel sure the following letter from Messrs. Parke, Davis & Co., of Detroit, will be of interest to your readers. The letter is addressed to myself, and says,—

"Referring to your article on 'Coca-Leaf Cigars and Cigarettes' published in the *Medical Times* (October 19, 1885), we beg leave to call your attention to the enclosed samples of coca-cheroots, which we have had made to meet the extensive demand you have created. A cheroot can be manufactured much cheaper than a cigar, and will of course retail at a lower price in proportion. Though containing about the same amount of coca as the cigar you sent us, the cheroot will retail at five cents apiece instead of ten cents apiece, which, we believe, is the price you quoted for the cigars.

"Please tell your medical friends that we would be happy to send samples to those who desire to try them."

In relation to the above letter, it seems to me that the cheroot fills every indication for the cigar, and I take pleasure in referring the profession to this well-known house, who will supply them with the very best quality of cheroot containing carefully-selected coca. As they are large importers of the drug, they have every opportunity of doing so.

But let me say at this time that it is my earnest desire to secure a very general expression of opinion concerning the use of coca in this form from the profession, and at an early date; and it would afford me great satisfaction to receive reports of trials, whether the results are favorable or otherwise; also to receive suggestions pertaining to the subject in any form.

Very truly yours,
F. E. Stewart.

Lock-box 248.

OBITUARY.

George Hamilton, M.D., died of apoplexy at his residence, in Philadelphia, October 30, 1885. Dr. Hamilton was born in this city in 1808, and was graduated in 1831 from the medical department of the University of Pennsylvania. He passed the most active part of his professional life as a country physician near Philadelphia, but for many years has led a retired life. He was an active member of the County Medical Society, of which he was elected President in 1868, and also a prominent member of the College of Physicians, to whose Proceedings he occasionally contributed. He wrote a memoir of his friend, the late Prof. J. A. Meigs, which he read before the State Medical Society. Of late years he took much interest in the question of the prevention of abuses in connection with the practice of vivisection.

A severe and sudden bereavement, the death by burning of a favorite daughter and a grandson by the burning of their residence on Pine Street last winter, undermined his health and strength. Owing to his temperate and regulated life, he was enabled to lead an active existence, although he was naturally rather delicate. He enjoyed full possession of his faculties up to the last day, and had just returned from church on Sunday morning when he was stricken. His wife, a daughter, and a son (who is a well-known artist) survive him.

J. A. Armstrong, M.D., a prominent physician of Camden, inspector of the State Board of Health for the counties of Camden, Gloucester, and Cumberland, died with cerebral apoplexy at his home, October 28, 1885. He was fifty years of age, was a member of several scientific societies, and at one time was coroner.

Samuel G. Armor, M.D., Dean of the Faculty of the Long Island College Hospital, and Professor of Practice in that institution, died of bronchitis October 28, 1885. He was a man of superior attainments, and was formerly a professor in the University of Michigan. He was an able writer and observer, and was not only eminent in his profession, but also was endeared to a large circle of friends by his agreeable manners and his sterling traits of character.

A. J. McKelway, M.D., late surgeon of the Eighth Regiment New Jersey Volunteers, died on Saturday, November 7, 1885, at his home, Williamstown, New Jersey, in the seventy-second year of his age. He was the father of Mr. George I. McKelway, a leading druggist of this city.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 25, 1885, TO NOVEMBER 7, 1885.

Major Ely McClellan, Surgeon.—Leave of absence granted in orders, Cavalry Depot, Jefferson Barracks, Missouri, October 30, is extended seven days. S. O. 254, A. G. O., November 4, 1885.

Major D. L. Huntington, Surgeon.—Detailed on Board to inspect Army and Navy Hospital buildings at Hot Springs, Arkansas. S. O. 245, A. G. O., October 24, 1885.

Major Henry McEldery, Surgeon.—Granted leave of absence for four months from November 1, 1885. S. O. 246, A. G. O., October 26, 1885.

Captain J. H. Patzki, Assistant-Surgeon.—Appointed member of Board to meet at Forts Jackson and St. Philip, Louisiana, November 5, 1885, to select a site for the new quarters for the ordnance-sergeants at those posts. S. O. 230, Department of the East, October 28, 1885.

Captain G. H. Forney, Assistant-Surgeon.—Granted leave of absence for two months, to take effect after the return from leave of Surgeon J. C. Baily (major). S. O. 87, Division of the Atlantic, October 24, 1885.

Captain R. G. Ebert, Assistant-Surgeon.—Ordered from Camp Grant, Riverside Park, New York City, to Fort Hamilton, New York Harbor, for duty. S. O. 237, Department of the East, November 5, 1885.

First-Lieutenant G. E. Bushnell, Assistant-Surgeon.—Assigned to duty at Camp Grant, Riverside Park, New York City. S. O. 237, Department of the East, November 5, 1885.

First-Lieutenant C. C. Barrows, Assistant-Surgeon.—In addition to his other duties, to take temporary charge of office of the Medical Division, Department of Arizona. S. O. 102, Department of Arizona, October 17, 1885.

First-Lieutenant C. B. Ewing, Assistant-Surgeon (Fort Leavenworth, Kansas).—To accompany Congressional Committee, of which Hon. W. S. Holman is chairman, in its visit and inspection through Indian Territory. S. O. 160, Department of Missouri, October 23, 1885.

First-Lieutenant F. J. Ives, Assistant-Surgeon.—Relieved from temporary duty at Fort Laramie, Wyoming, and ordered to Fort D. A. Russell, Wyoming. S. O. 106, Department of the Platte, October 22, 1885.

First-Lieutenant E. R. Morris, Assistant-Surgeon (recently appointed).—Assigned to duty at Fort Bayard, New Mexico. He will continue on detached service under orders of District Commander. S. O. 160, Department of Missouri, October 23, 1885.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM OCTOBER 25, 1885, TO NOVEMBER 7, 1885.

Medical-Director David Kindleberger.—Granted leave of absence to June 30, 1886, with permission to leave the United States.

Assistant-Surgeon F. W. F. Wieber.—To remain on Receiving-Ship "Vermont" until May 15, 1886.

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, NOVEMBER 28, 1885.

ORIGINAL LECTURES.

CLINICAL LECTURE
ON ACUTE MANIA AND HYSTERICAL MANIA.

Delivered at the Philadelphia Hospital

BY CHARLES K. MILLS, M.D.,

Neurologist to the Philadelphia Hospital, and Consulting Physician to the Insane Department of the Hospital; Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic.

GENTLEMEN,—As soon as the doors of the hall were opened, we were greeted with noisy exclamations, alternating with singing and laughing, which, as you now observe, came from the patient before us.

The history of this patient, as furnished to me by Drs. Richardson and Avery, is as follows:

B. T., female, aged 25 years, single, German, her occupation that of a domestic, is a delicate, frail, and extremely emaciated girl, of medium height and slender build. She is of fair complexion, with blue eyes; the pupils are equally dilated. Her head is well formed and natural in size, with light flaxen hair. Her countenance is pale, and her expression peevish. She is of a nervous temperament.

Physical examination shows a dulness of percussion-note over the apex of right lung. There is also an exaggerated respiratory murmur, but otherwise the thoracic organs and the abdominal organs are apparently in a healthy condition. Her pulse is rapid and feeble; her skin rough and dry, with redness over the finger-joints and around the hip. The knee, elbow, and middle joints of her fingers are flexed and rigid. There are no bruises or other marks of injury about her person. Her tongue is slightly coated.

In June of the present year the patient began to neglect her work. She was listless, and seemed unable to fix her mind upon her occupation, but stood around without accomplishing anything. Shortly afterwards she took to her bed, where she has since remained. She was not thought to be insane by her friends until about four weeks ago, when she began to be irritable, capricious, irrational, and delusional. She gave her clothes away, claiming that she was rich, that she owned the whole world. She asserted that she was finely educated, that she was specially gifted. These and various other delusions of a pleasing nature presented themselves. Two weeks ago she became noisy at night-time, crying, singing, screaming, etc. She believes that the trouble with her joints came on as a punishment for attempting to commit suicide; thinks that she was bound hand and foot to prevent her from again undertaking such a sin.

On admission into the hospital, her delusions were numerous, but not unpleasant in character. She is now irritable and easily excited. Her mind is active, memory good. She has no history of epilepsy, and no symptoms of ordinary or general paralysis. Since her admission here she has been capricious and not easily pleased; she thinks that she owns the place, and that all the people in it are under her command. She orders barrels of California wine, bottles of champagne, beer, and various other things, saying that they have been sent her by her father. She accuses other people of the misdemeanors which she herself commits. She rolls out of bed and says that the doctor has thrown her out. She screams and cries nearly every half-hour, protesting that she is starving to death. When food is brought her she takes but a few spoonfuls, and immediately after being fed will declare that she has had no food for two or more days. Usually she is noisy and filthy at night, crying and talking in her sleep; although during Saturday and Sunday nights last past she was quiet and clean. Hydrobromate of hyoscine, in doses of one-sixty-fourth of a grain, has been given at bedtime. This induces sleep throughout most of the night; but the sleep is of a troubled character, and on awaking in the morning she maintains that her father has made her work hard all night.

The patient has been a temperate, hard-working girl, and the present symptoms of insanity are the first she has ever shown. Her insanity is said to have been caused by disappointment in love, which occurred a little more than a year ago. She attempted suicide in January, 1885. She has had amenorrhœa for about one year, and a hacking cough for at least six months. A sister died of consumption, and another was insane. Since last June she has lost flesh rapidly.

From this history it will be seen that the patient's sickness has come on gradually, that her condition has varied somewhat during the few months since she was first attacked, and that very recently she has developed marked mental excitement, which persists. Let us study the symptoms as they present themselves with the patient before us,—her present state, mental and physical.

In the first place, you notice that the patient is in a condition of *emotional* excitement: her emotional nature is exaggerated. This excitement or exaltation

exhibits itself in speech and movement. She is noisy; she is voluble; her speech is rapid; she shouts and declaims; she tells us that she will sing to us; without encouragement she attempts to sing. On the whole, her excitement is of a joyous or agreeable type; she is pleased with herself, and, as you see, is at the present moment in excellent spirits.

Secondly, she is *incoherent*. Incoherence, as some of you know, may be either of words and phrases or of ideas; that is, it may be verbal, or it may be logical or rational. In this patient's case the incoherence is evidently not verbal. She expresses herself volubly, but uses connected words and phrases: her incoherence is of ideas. While we have been here talking with her and about her, she has passed from one idea to another probably a dozen or more times; but the sentences are complete in themselves, and she even has several connected sentences relating to the same thought: this, however, appears to be as far as she is able to go.

Thirdly, she has *delusions*. They are of an expansive type. I ask her if she is married. "Oh, yes, I am married, and I had ten children in ten years." She is not married at all. The next moment she tells us she has been married twenty years. She says, also, that she has many fathers and mothers. Dr. R. is her father and Dr. A. her mother in this country, and she has another father and mother in Germany, and a father and mother in heaven. On remarking that she is thin, she replies, "Oh, no, I am not thin; I am six feet tall." Asking her about her means, she tells us, "I have a thousand dollars; my father gave me a million dollars. I own the whole world; the constitution is the world." She continues, "I will sing for you. I can sing for you 'My father and mother were Irish, and I am Irish too,'" etc. I ask her, if she is so wealthy, why does she stay here in a hospital? She answers, "I own this place; this is a great palace, which belongs to me, and if the doctors don't do as I say, I will get somebody else." [These remarks were made in a rapid, loud, declamatory manner, grimacing and gesticulating as much as the condition of her hands and arms would permit. She sang with a loud voice, interrupting frequently with sharp questions and funny or sarcastic remarks.]

This patient, then, has delusions, and also delusional states. These delusions vary somewhat in character, but within narrow limits. They seem to cluster around an exaggerated idea of her own wealth, importance, strength, and powers; she does not attempt to explain or justify anything that she says, but rapidly passes from one remark to another.

Sometimes the patient will have fits of crying and worrying, although these have not appeared to-day; but she has no persisting state of depression. The state at present is, on the whole, one of elevation, and undoubtedly more or less excitement is always present. Sometimes she is in a condition of true delirium, although this does not last long. When in this condition she has marked incoherence, excitement, more delusions, and a greater tendency to movement, with acceleration of pulse, but without, I believe, so far as has been noticed, any increase of temperature.

Let me next say a few words about her physical condition. As you have learned, she has a family history in which both phthisis and insanity have been present. Some physical evidences of phthisis are shown in this patient. She is emaciated and weak, although she claims that she is both fat and strong. Her pulse is frequent and feeble; her heart's action is somewhat rapid and tumultuous, but I cannot positively make out any murmur; she is pale and anæmic-looking.

Certain special physical symptoms are here present. In both the upper and lower extremities are marked contractures. All of her fingers are rigidly semi-flexed and cannot be straightened. Her forearms are only partly flexed upon the arm, and can be straightened, although she complains of pain when this is done. Her lower extremities show contractures at the knees and feet, the latter being in a partial equino-varus position, most marked in the right leg. She complains bitterly if any attempts are made at reducing these contractures. Inspection shows vivid redness of the small joints of the fingers, but not much swelling or heat. Everything goes to indicate that this affection is rheumatic or rheumatoid gouty in character. It is possible that either the phthisis or the rheumatism may have some etiological connection with the mania here present. Some authors describe both a *phthisical* and a *rheumatic* insanity, which

take various forms. We are not to-day, however, so much concerned with determining the character of the patient's disorder from an etiological as from a symptomatological point of view.

The patient eats at times somewhat ravenously. At present she sleeps fairly well, although she will awaken several times in the night, and when she does so usually asks for food or drink.

What are the nature and character of this case? That the patient is insane need not be said. As to the form of insanity, the excitement and incoherence, which are such prominent features, would decidedly incline us to the view of mania. Might it not, however, be some other form of mental disorder? Delusions of importance, of wealth, or of grandeur, and also incoherence, are present in several forms of insanity. It is often necessary to separate even melancholia from mania. At times cases of melancholia have periods of wild excitement, due to the depressing delusions of which they are the victims. They are fierce and agitated because of the horrors which surround them and the dangers which menace them or those that they love. This is *melancholia agitata*, a delirious melancholia, not mania in a true sense. This patient's excitement does not appear to be due to any cause of this kind: therefore we may exclude melancholia.

In paretic dementia, or general paralysis of the insane, as some of you well know, the so-called delusions of grandeur are among the most common and characteristic symptoms of many cases, although they are not always present. Paretic dements will often tell you, as this patient has told us to-day, that they are strong, that they are tall, that they are swift, that they are millionaires, that they have great power and authority, that they own a nation or the universe. Their delusions, like those of this woman, are not defended and are not systematized: they can be led, as this patient has been led, from one delusion to another. Symptoms such as these, however, will not enable us to make a diagnosis of paretic dementia. These expansive delusions may be present in mania of several forms. If this patient were a case of general paralysis of the insane, she would have certain physical symptoms which are here entirely wanting. The history of the onset and progress of her case would be different. Paretic dements usually have had attacks of paresis (fleeting, it may be), or of convulsions or convulsive seizures. They present certain oral symptoms, a peculiar staggering, hesitating speech, with tremor of the lips and tongue, and often a drooping of one side of the face. These phenomena are absent in this case.

In monomania the patients sometimes have episodes of excitement or delirium. In this patient, however, the elementary evidences of the existence of true monomania are absent. She has not now, and never has had, any delusions of an organized and systematized character, delusions around which she could weave a chain of more or less connected argument. Melancholia, paretic dementia, and monomania may then all be excluded. Epileptic mania may also be set aside. The history of epilepsy in any form is not here present.

I believe, therefore, that we must conclude that we have here to deal with a form of mania. The next question that confronts us is whether it is true mania or a form of the so-called *hysterical mania*. This is a diagnosis that it is well worth while to make; and, indeed, it may be highly important to determine. Some may tell you that it is impossible and of little moment to distinguish between common mania and mania of the hysterical variety; but with this view I do not agree.

The whole question of hysterical insanity is one that is wrapped in more or less difficulty and obscurity. The hysterical insanity of one authority may not be that of another. The older and some of the more recent writers on insanity do not recognize hysterical insanity as a distinct form of mental disease. Morel and Skae, in their etiological classification, and Hammond, Spitzka, Mann, and Clouston, in their recently-published works, give it a place. Krafft-Ebing not only recognizes hysterical insanity as a distinct form of mental disease, but, after the German fashion, subdivides it quite minutely. Spitzka speaks of chronic hysterical insanity as an "intensification of the hysterical character to which a silly mendacity is frequently added, and develops *pari passu* with advancing deterioration." Hammond, under hysterical mania, includes several different and somewhat distinct mental disorders.

The fact that hysteria may occur as a complication of various forms of insanity which very properly are not classed as hysterical insanities is often overlooked. Hysterical manifestations among patients suffering from some well-recognized, non-hysterical forms of insanity are of comparatively frequent occurrence. Paralysis, contracture, hysterical joints, hysterical neuralgias, convulsions, cataleptoid phenomena, and tremor are among the hysterical manifestations which have fallen under my personal observation among the insane of various classes.

A remarkable case of hysterical motor paralysis was observed by me at the State Hospital for the Insane at Norristown, and notes of the case have been furnished me by Dr. Alice Bennett, the Superintendent. This patient was an intelligent single woman, about 35 years of age, of good family, and well educated; she had been a teacher and a writer, and became insane through family and business troubles. When only eight years of age she was paralyzed for two and a half years, and had had at times during her life, before becoming insane, attacks of partial or complete unconsciousness. Prior to coming under observation she had been an inmate of an English private asylum. She was sick on shipboard coming to this country, and on her arrival was in a state of delirium and insomnia, with attacks of loss of sight. Four months later she developed mania with suicidal inclinations. Just before the development of this maniacal condition her lower limbs became comparatively helpless, and soon after she entirely lost their use. I found her in this condition. Examination showed no change in knee-jerk, electrical reactions, nutrition, or genito-urinary conditions, which led me to diagnosticate the absence of any organic spinal trouble. The case was pronounced one of hysterical paralysis, and it was prophesied that she would eventually completely recover, probably suddenly. For one year her paralysis remained, her mental condition varying greatly during this time: sometimes in a lethargic state; sometimes with variable delusions and delirium; occasionally violent and destructive, again peaceable and pleasant; sometimes requiring strong anodynes and hypnotics. Fourteen months after her paralysis began, she one day suddenly threw away her crutches and ran up and down the corridor of the hospital. From that time on she walked without difficulty, although her mental condition did not entirely clear up. I could give other detailed illustrations, but time will not permit me to do so. I simply wish to impress the fact that because you have hysterical manifestations in a case of insanity it should not necessarily be diagnosticated as one of hysterical insanity. Monomania, melancholia, mania, paretic dementia, epileptic insanity, and other forms of mental disorder may at times have a hysterical tinge or present hysterical episodes.

As I have already said, the whole question of hysterical insanity is one of great difficulty. The psychical element is probably at the root of all cases of hysteria; but this does not justify us in declaring that all cases of hysteria are insane. In practical professional life we must make practical distinctions. In the matter before us, distinctions are necessary to be made for legal as well as medical purposes. It might be right and proper to place a case of hysterical insanity in a hospital or asylum under restraint; but no one would dare to claim that every case of hysteria should be so treated.

Although my experience with all forms of hysteria has been large, I find myself hesitating as to the best manner of discussing and subdividing hysterical insanity. It is probably as good a method as any to divide it first into an *acute* and a *chronic* form, although in the chronic form we may have the acute variety as an episode or a link in a chain of events. In other words, an attack of acute hysterical mania may occur more or less frequently in the course of chronic hysterical insanity.

By acute hysterical insanity, or hysterical mania, I mean a disorder usually, in part at least, purposive, and characterized by great emotional excitement, which shows itself in violent speech and movement, and often also in deception, simulation, and dramatic behavior. The phenomena indicated by this definition may constitute the entire case, or, in addition, the patient may have, at intervals or in alternation, various other phases of grave hysteria, such as hystero-epileptic seizures, or attacks of catalepsy, trance, or ecstasy.

In chronic hysterical insanity we have a persisting abnormal mental condition, which may show itself in many ways, but

chiefly as follows: 1. A form in which occur frequent repetitions, over a series of years, of the phenomena of acute hysterical insanity, such as hysterical mania, hystero-epilepsy, catalepsy, etc. 2. A form in which sensational deceptions, sometimes undoubtedly self-deceptions, are practised. Under this head come the wonderful cases often recorded in newspapers, in which young women detail alleged assaults made upon them, make accusations of rape, or are the central figures in extraordinary occurrences, in which ghosts, acts of incendiarism, and the like are prominent.

In a case of chronic hysterical insanity you may have both of these forms commingling in varying degree. My time is too limited to allow me to go further into this interesting subject. I will now return to a discussion of acute hysterical mania, and, after showing you a case, will attempt to formulate the differential features which separate it from a case like the one that has just been studied.

This patient, G. ——, is a seamstress, 21 years of age. Although young in years, she is an old hospital rounder. She is now a patient in the Wards for Nervous Diseases of this hospital, which are not a part of the Insane Department. She has at various times been in almost all the hospitals of this city. At different times and in different institutions she has been treated for such alleged serious affections as fractured ribs, hemorrhages from the lungs, stomach, and vagina, gastric ulcer, epilepsy, apoplexy, paralysis, anæsthesia of various localities, amenorrhœa, dysmenorrhœa, and fever with marvellous variations of temperature. She has become the bane and terror of every one connected with her treatment and caretaking. She has developed violent attacks of mania, with contortions and convulsions on the streets and in churches. Considerable sums of money have been collected for her at times by those who have become interested in her as by-standers at the time of an attack or have heard of her case from others. She has made several pseudo-attempts at suicide. Recently an empty chloroform-liniment bottle tumbled from her bed at a propitious moment, she at the same time complaining of pain and symptoms of poisoning. She has refused to partake of food and has been discovered obtaining it surreptitiously. Her large and prolonged experience with doctors and hospitals has so posted her with reference to the symptomatology of certain nervous affections that she is able at will to get up a fair counterfeit of a large variety of grave nervous disorders.

She is now just passing through one of her attacks of hysterical mania, which was preceded by a series of hysterical phenomena, such as vomiting, hemorrhage, aphonia, ovarialgia, headache, and simulation of fever. She began by crying and moaning, which was kept up for many hours. She fell out of bed apparently insensible. Replaced in bed, she passed into a state closely simulating true acute maniacal delirium. She shrieked, cried, shouted, and moaned, threw her arms and legs about violently, and contorted her entire body, snapping and striking at the nurses and physicians in attendance. At times she would call those about her by strange names, as if unconscious of the true nature of her surroundings. Attacks of this kind were kept up for a considerable period, and after an interval of rest were repeated again and again.

This is simply a sketchy outline of the case. In private practice I now have under my care two somewhat similar cases, in one of which the maniacal or pseudo-maniacal excitement is the only prominent feature; in the other, these attacks are accompanied by or alternate with states of trance, ecstasy, pseudo-somnambulism, and catalepsy.

In what do these cases differ from the case of true acute mania the examination and discussion of which have occupied the first half of our hour to-day?

In both cases we have great excitement, shown in speech and movement.

In hysterical mania the outbreak of excitement is generally sudden, although prodromic manifestations are sometimes present, and this point of difference is not one to be absolutely depended upon. In acute mania incoherence and delusions or delusional states are evidently more genuine phenomena than in hysterical mania. In hysterical mania hallucinations or delusional conditions may be present, but they differ from those of acute mania. The hallucinations of hysterical cases are apt to be of a peculiar character. Frequently such patients see or say that they see animals,—rats, toads, spiders, and strange beasts. Their delusions have the appearance of being affected in many cases; very often they are fantastical; and sometimes, at least, they are spurious or simulated. In these cases special grave, isolated hysterical symptoms often occur during the progress of the attack,—such phenomena, for instance, as obstinate mutism, aphonia, pseudo-coma, and trance. These are usually wanting in acute mania. Cases of hysterical mania will threaten, or apparently attempt, suicide, but their attempts

are not genuine,—they are rather acts of deception. In acute mania, under the influence of excitement or of certain delusions, the patients, if not carefully watched, may take their lives. Cases of acute mania will sometimes starve themselves, or become very much reduced and emaciated from a refusal to take food; sometimes, on the other hand, they eat voraciously. The hysterically insane will threaten to starve themselves, but only in extremely rare cases will they really do so. As a rule, considering the amount of mental and motor excitement through which they pass, their nutrition remains good. Acute mania and hysterical mania terminate differently. The former, under judicious treatment and management, may gradually recover; sometimes, however, it ends fatally. This is specially likely to occur if the physician supposes the case to be simply hysterical and the administration of nourishment is neglected in the early history of the case. Hysterical mania very seldom has a serious termination unless through accident or complication. In acute mania sleeplessness is commonly a prominent and distressing symptom, and often persists day and night. In hysterical mania the patients, as a rule, will get a fair amount of sleep some time in the twenty-four hours. I have noticed the peculiarity that in some cases of hysterical mania occurring in private practice the patients have had their worst attacks early in the morning, after a good night's rest.

In the treatment of acute mania the chief indications are to produce sleep, control excessive excitement, and thoroughly nourish the patient. Hydrobromate of hyoscine in doses of $\frac{1}{80}$ to $\frac{1}{100}$ of a grain, fluid extract of conium in doses of from five to twenty minims, and a combination of the bromides with chloral, are the most useful medicinal remedies. Tepid baths are also useful. The patient should be fed systematically, and an amount of nourishment even in excess of that which would be taken in health administered. In hysterical mania the treatment resolves itself largely into moral measures and the management of particular symptoms.

A New Light.—The Ideal Electric Lamp, with its circular hollow flame, is said to give a light of fifty-candle power. It is ornamental as well as useful.

MEDICAL SUPERVISION IN STUDENT LIFE.

BY CHARLES McINTIRE, Jr., A.M., M.D.,

Lecturer on Hygiene, Lafayette College.

Read before the American Academy of Medicine, October 28, 1885.

IT does not require a very profound study of history to discover that the manifestations of the habits of man and of his modes of living have changed with the advance of years and the march of civilization. Whether or not the motives underlying and impelling these manifestations have undergone any change, or whether it is simply a regrouping of the old factors, is a question that would require a deeper search and would lead us in a different path than is contemplated.

Let us be content to accept the conditions without any regard to questions of cause and effect. It is evident that the occurrences of the life of an average person in this the last quarter of the nineteenth century are different in many ways from the happenings of a corresponding person at the opening of the century. The opening up of the various fields of knowledge has so broadened the world; the improvements in modes of locomotion and correspondence have so narrowed it; the advances in printing processes, in domestic architecture, and the "modern improvements;" the ease for acquiring the rudiments of knowledge, and other factors equally patent and potent, have made the whole land the metropolis. *Urban* and *rustic* have largely lost their significance. With these conditions the question suggests itself, whether this change of environment has caused any change in the man which would require new observation and additional care by the physician. I desire to discuss this question with as little theory as possible, and will consequently exclude the hypothesis that if the fathers possessed the same means for investigation, or had had their attention called to the conditions, they would have found and described what is now called new: indeed, "a right and charitable frame of spirit" towards the elders would exclude its entertainment.

Have we any testimony regarding the change of man physically? I need but remind you of the writings of our late and

lamented fellow, Dr. Beard, upon neurasthenia; of the many series of investigations upon the eyes of the people, especially of those in schools and colleges; of a similar investigation by Dr. Sexton on defective hearing; of the valuable observations of Dr. L. B. Tuckerman in the public schools of Cleveland. To these one may add a mere mention of the increase of suicides, of a greater number of hospitals for the insane, and of patients inhabiting them, to show that there is, apparently at least, a change in the condition of man, a deterioration from the health normal. And if this change tends to neurasthenia, to the development of defective eyesight or audition, to an inability to continue on in school life,—if it enters in the slightest degree as an etiological factor in the increase of self-murder, or of increasing the practice of alienists,—it is not a change to be admired or desired.

There follows a duty for those of us who are placed on the watch-towers. We must either sound the alarm of the enemy's approach, or prove conclusively that the conditions alluded to are but a mere mirage and the enemy a phantasm.

Assuming for the present purpose the accuracy of the conclusions of so many and able observers, can we, in the first place, discover aught that might be taken as causative, and, in the second, suggest anything looking towards a remedy? While indeed "tempora mutantur," except to the astronomer, the days of man remain unchanged, containing precisely eighty-six thousand four hundred seconds, and the body of man, as of yore, demands rest and exercise. There is a wear and a tear, which of necessity takes place in almost a mathematical ratio directly to the work and the worry, and there must be a repose and a repair, or somewhere the machinery will give way. It is quite generally asserted that there are greater demands upon one's time in the nowadays than of yore. The school-boy, *e.g.*, has the number of his studies multiplied and the length of his tasks added to, and, as a consequence, rest and recreation hours are apt to be intrenched upon. And instead of keeping up or increasing one's strength, the capital stock is drawn upon, often greatly affecting the solvency of the individual. Under the former *régime* rest and recreation brought recuperation and development. The body grew healthfully and symmetrically, because it had opportunity so to do. At the present the body-powers are frequently taxed simply to exist and to resist the excessive drain upon them. If these statements express the facts in the case, a clue is furnished us for the cause: then, what shall be done? Go back to the older and physically less exhausting plan? To attempt this would, I fear, be but to copy Mrs. Partington mopping the ocean. What remains, then? The application of the principles that have marked the advance of civilization in other matters, to the care of the body. While man has been adding improvements and conveniences to that which surrounds him and to himself mentally, æsthetically, yes, even gastronomically, the maintenance of a sound body has been for the most part left to the methods of the former generations. Crab-like, he has outgrown his shell, and it is high time he searched for another.

Scientific progress has not as yet shown any way by which a man can diminish the proper amount of rest and thrive. Our attention, therefore, must wholly be devoted to the recreative. Can it be so arranged that the body may have such attention paid to it that there may be proper development in the diminished time that can be given to it?

Beginnings have been made looking to this end, starting possibly with the revival of the gymnasium in Germany and the development of Turn-Vereins, and the expansion of movements in Sweden, together fusing into lighter gymnastics. Amherst College some twenty-five years ago introduced a regular compulsory exercise, after measurements of the body more or less complete, and they have been adding to the care of the physical examination and more carefully directing the exercise to strengthen the weaker parts in the years that have followed. Dr. Sargent, of the Hemenway Gymnasium of Harvard University, is known as the author of a system of regulated exercise looking to this same end; and there have been other workers in the same field. In 1874 the public schools of Brussels were placed under direct medical inspection, five physicians devoting their entire time to the inspection of buildings and pupils, keeping accurate anthropometric records, to instruction on the care of the body, including gymnastics, and to the prevention of the spread of disease; and the results ob-

tained were in every way satisfactory. There have been other attempts at medical supervision, more or less complete, but the result of their labors is not at hand.

The necessity of an early examination of the eyes and ears of children, in order to take the proper care of them in school life, has been urged for some time by physicians interested in these subjects.

It seems, then, that the best way to fight the fire is with fire. Science, in its progress, makes a greater demand upon the body. Let us bring the results of this scientific progress to our aid in the maintenance of health and for the development of sturdy, healthy bodies. At the beginning of the school age, if not before, the child should have a thorough physical examination, and the weak points made known. Then, as a part of the school course, let systematic graded exercise be given, dividing the scholars in classes according to the physical condition of the child, after the same manner that they are divided in classes for mental improvement. And from the first the child should be kept under trained supervision guiding and directing its growth. Of course such a scheme as this would involve an outlay of money by no means inconsiderable; for it is to be hoped that the already too generous physician would not make an additional contribution from his capital to the many he is already making, far in excess of the gifts to public good of any other calling. But the necessity of State Boards of Health is everywhere recognized. Even in Pennsylvania our stolid Keystone legislature has at last given way. And certainly the need to develop healthy men is no less a state duty than to prevent disease or to perform any other function given to health boards. Of course it would be of equal advantage to the young people in business as for those of the same age in the higher institutions of learning. But our government could not probably be made sufficiently parental, nor is it desirable that it should be. If the proper bend is given to the twig in school before entering upon the more active pursuits of life, possibly the tree will keep inclined in the right direction, and the early habits lead to a correct estimate of the worth of a strong body and the adaptation of proper means to keep it so.

An after-thought, hardly of the nature of a corollary, but rather a scholium. There is a general, although excusable, ignorance of the object to be attained, and the means to accomplish this desired end in a present-day gymnasium. I quote from memory an interview, reported in a newspaper, with Dr. White, director of the gymnasium of the University of Pennsylvania, to show the object: "In ordinary training the desire is to bring into prominence the best parts of a man. The man with strong loins and back is put on the crew, and the quick runner will be entered for the foot-race. In the new [University of Pennsylvania] gymnasium training the weak parts are sought out, and the weak-backed would be put to the oar [not for a race], and the spindle-shanked to the running-track."

The system of gymnastics to bring this about involves the use of very light exercise, for the most part the use of variations of a pulley and weight, by which almost any set of muscles can be brought into use at will. By the proper adjustment of the weight an accurately graduated series can be arranged adapted to all degrees of strength or of weakness. The various paraphernalia usually associated in the mind of *οἱ πολλοι* with a gymnasium are used voluntarily, and even then under direction. Experience shows that there is a fear upon the part of the parents of weak young men lest the gymnasium course should prove injurious; yet these are the ones most requiring it, they are the most carefully directed, and are under the closest supervision.

The strong and active will, under the enthusiasm of a good instructor, almost take care of themselves. The healthy and lazy assist in the moral as well as physical development of the director, while the weakling in any way is a subject of his especial care, and every increase in health-power or strength becomes a subject for special jubilation.

Now, if there is not a serious flaw in the facts mentioned or in the conclusions arrived at, there remains a duty for us. We should in every way possible so enlighten the unprofessional mind that the value of bodily care in school life may be seen by all, and that which at the present seems hardly more than a dream shall become a fixed fact.

A CASE of Cæsarean section after the death of the mother, the child surviving, is reported by Dr. J. Mack Hays in the *Medical Record*, p. 563.

A CASE OF SCIRRHUS OF THE COLON—LAPAROTOMY.*

BY FERDINAND H. GROSS, M.D.

THE specimen of intestinal tumor which I have to exhibit was removed from the body of a man whom I saw a number of times during his last illness, in consultation with Dr. C. H. Gardner, the attending physician, and Dr. J. M. Da Costa. The following is prepared from the notes of the case furnished me by the former.

Mr. C. T. S., aged 38, a native of Philadelphia, of healthy parentage, fine physical development (height five feet seven inches, normal weight one hundred and seventy pounds), of strictly temperate habits, and by occupation a stove-pattern manufacturer. He had always led an active life, and occasionally took part in athletic games. In his family record there appeared to be no points of pathological interest, except that an aunt died of cancer of the face.

Fifteen years ago he had an attack of jaundice, with severe headache. The liver was perhaps slightly enlarged, and the bowels were constipated. After a course of medication lasting from three to four weeks, he recovered.

It was his habit to indulge in yachting on the Delaware River, and four years ago he extended this sport late into the autumn and contracted malarial fever. Under Dr. Gardner's treatment he again recovered, after an illness of two weeks' duration.

The patient's last sickness dates from the 1st of June, 1885, nearly five months prior to his death. He had been engaged all day in a yachting-contest, and returned home very much exhausted. From this time he continued to complain, and soon began to lose flesh. With a view of regaining his health, he made several visits during the summer to Cape May and Atlantic City; but no improvement resulted from these periods of rest and sojourn at the sea-shore. Dr. Gardner states that his symptoms were rather vague. He complained mostly of an uncomfortable feeling in the region of the stomach and liver, and this occasionally amounted to a dull pain, but it was not of a darting or shooting character. He would frequently say, "There is something wrong with my belly." As the case progressed, the patient would locate the pain more in the epigastric and umbilical regions, and occasionally in the left side, rather than in the region of the liver.

About the 1st of August the symptoms were regarded as being of a dyspeptic character, and were partially relieved by the use of pepsine and subnitrate of bismuth. Whilst he obtained no complete relief, he was not incapacitated from attending to his usual business. In the latter half of September he complained for the first time of severe cutting pains in the left hypochondriac and lumbar regions. The nature of these pains was so different from the patient's previous sensations that he described them as "a new departure." On the 24th of September, Dr. Gardner discovered an area of abnormal dulness extending over and beyond the region of the spleen. By the administration at this time of mild cathartics and quinine, and by the application of external irritants, the pain was considerably relieved and the area of dulness diminished. He continued to go to his place of business, but by the 1st of October he had lost thirty pounds in weight.

On that day Dr. Gardner brought him to my office for consultation. The history of the case as then obtained was in the main as has just been given. A physical exploration evinced nothing abnormal about the thoracic organs. The abdomen was somewhat distended. In the left hypochondriac region there was abnormal dulness on percussion, and something like a hardened mass could be indistinctly felt. Pressure upon this point caused some discomfort, but no acute pain. Whether these abnormal signs were due to a morbid growth, to accumulation of fæces, or possibly to an enlarged spleen, I was not able to determine definitely. The history of the case, and especially the marked loss of flesh, pointed rather to the existence of organic and possibly malignant disease. Pressing manipulation over the liver was readily tolerated by the patient, and that organ showed no well-marked change in size. His complexion was sallow, but the conjunctiva was not tinged. A subsequent examination of the urine showed it to be non-albuminous. A mild purgative was ordered, and, as malarial infection was suspected, ten grains of quinine were directed to be taken every other day.

I heard nothing further of the patient until I was requested to meet Dr. Gardner at the bedside, nine days later. I learned then that the laxative medicine ordered at the time referred to had produced two free alvine evacuations and afforded considerable relief; but after that the bowels again became bound up and the same dull aching pain continued. For five days all efforts to open the bowels had failed. The patient continued to go about, and on the 7th of October called at Dr. Gardner's office. He complained now of a bearing-down sensation, with a frequent desire to go to stool, but without obtaining any relief. On that night a large enema of soapy water, with castor oil, turpentine, and olive oil, in all about a quart, was injected. This produced one free evacuation, but the character of the dejection was not ascertained. Feeling somewhat relieved, he returned to his business the next day. During

* Read before the Philadelphia Academy of Surgery, November 2, 1885.

the same evening, however, he began to vomit, and at 10 P.M. sent for his physician, who found him vomiting and retching violently and in great pain. The stomach would not retain anything. The drinking of warm water relieved the distress somewhat. An enema was again used, which soon came away, bringing with it only one small lump of fæcal matter. A large flexible male catheter was next introduced and passed beyond the sigmoid flexure, and by this means a quart or more of fluid was injected into the bowel, but with no better result than before. The abdomen was now directed to be freely rubbed with warm castor oil, and to be covered with flannels dipped in hot water. After this the patient rested comfortably for the rest of the night; pulse 82, temperature normal.

On the next day, the 9th of October, as already stated, I was requested by Dr. Gardner to see the patient. We found him resting comparatively easy; the bowels had not been moved. The abdomen was somewhat swollen, and, although considerable pressure with the hand was easily borne, the hardened mass which I had discovered at my first examination, nine days prior to this, could not now be felt as before, and seemed to have disappeared. Abnormal dulness, however, over the region of the spleen still existed.

It was thought that the change in the physical signs might be accounted for by the fact that the patient had had several alvine evacuations since my previous examination, and that there might have been an impaction of fæces in the colon. As there was no fever, the pulse only 82, no great tenderness of the abdomen, and as enemata had latterly failed to produce an evacuation, it was agreed to try another mild cathartic by the mouth. A mixture was ordered containing sulphate of magnesia, aromatic syrup of rhubarb, and tincture of hyoscyamus and belladonna. A dose was given every hour. Towards evening it was found that he could not retain the medicine, and was again vomiting frequently. Hot applications were again made to the abdomen, and a little beef-tea and milk with lime-water were occasionally given. Later on a Dover's powder was administered, and he again passed a quiet night. On the 10th, one-fourth grain of calomel was given every two hours until two grains were given. There was frequent desire to go to stool, accompanied with tenesmus, but no evacuation followed. In the night one grain of opium in the form of a rectal suppository procured good rest. On the 11th he was again restless and occasionally vomiting. The opium suppository was repeated with good effect. The real cause and nature of the intestinal obstruction remained obscure. There never had been singultus or any vomiting of fæcal matter. Tenderness of the abdomen had not yet very markedly increased. He was next given one-third grain of aloin every two hours until he had taken four or five doses, but there was no effect upon the bowels.

On the 13th Dr. Da Costa joined us in consultation. Various causes of intestinal obstruction were considered, such as intussusception, volvulus, fæcal accumulation, enteroliths, gall-stones, stricture, tumors, chronic lead-poisoning, etc. The early belief of the attending physician, that the trouble was due to a slowly-forming stricture or to some obscure morbid growth, seemed to be the most tenable position, but was not made out with entire clearness. The early history of the case and the steady loss of flesh pointed strongly in that direction. Our next step in the treatment was the injection of a pint of warm olive oil, the nates to be kept elevated and the shoulders depressed. The oil was retained one hour, when it came away with some gas but no fæcal matter. Vomiting (which was never of a fæcal character) returned, and there was increase of pain. The suppository of opium never failed to give relief from the latter. On the 14th there was no improvement. Dr. Da Costa met us again on the 15th and 16th, but all our efforts to overcome the trouble were futile. At one time about two quarts of fluid were injected by means of the long tube, demonstrating that the obstruction was not in the rectum, sigmoid flexure, or lower portion of the colon.

At our final consultation with Dr. Da Costa, on the 19th, the question of laparotomy was considered. It was clear to all that the patient could not survive much longer under the existing conditions. Death seemed absolutely certain, and the operation, although a desperate step, might, in view of the unascertained nature of the obstruction, afford a slight chance for life. This view was clearly stated to the patient and his family. Their consent having been obtained, I at once undertook the operation, Drs. Gardner and J. M. Barton assisting. The patient was etherized at 1.15 P.M., and the abdominal cavity opened by an incision in the linea alba extending from a point two inches and a half above the umbilicus, around the left of that point, and two inches below it. A large portion of the small intestine, greatly distended and showing marks of inflammation, protruded from the wound. The operation was performed under antiseptic precautions; the spray, however, was not used. The hand was inserted into the abdominal cavity in search of the obstructed point. Deep in the left hypochondriac region, tightly bound down posteriorly, a hard nodular tumor was felt. It was clear that it involved and occluded the adjoining portions of the transverse and descending colon. It was held to be some form of cancer, and, as nothing could be done with it, we decided to puncture the protruding small intestine at a low point, allow it to empty itself, and afterwards stitch it to the lower end of the abdominal wound, establishing a fæcal fistula.

From the opening made in the gut, gas of an exceedingly offensive character and fully two quarts of thin, dark fæcal matter escaped. It required great care to prevent the abdominal cavity from becoming polluted. The protruding intestine was carefully washed with an antiseptic solution of bichloride of mercury, returned within the abdomen, and the wound closed down to the point of the fæcal fistula. The patient recovered nicely from the effects of the ether; about 3 P.M. was given morphia hypodermically. At seven he appeared bright, quite talkative, and took some beef-extract with a relish. Morning temperature 100°, pulse 120; evening temperature 103.4°, pulse 130. Urine drawn off with the catheter.

20th.—From 2 to 3 A.M. he was in great pain and was vomiting. An opium suppository gave decided relief, and he retained some beef-tea and a little brandy. Temperature 102.4°, pulse 140. Some fæcal matter oozed from the fistula, and the urine was again drawn off. During the afternoon the pulse began to fail, and the extremities became cold. He remained conscious until 8 P.M., and died shortly before midnight.

By an examination of the specimen on the table, it will be found that the diseased mass involves and completely encircles the adjoining portions of the transverse and descending colon. The occlusion of the gut is not absolute, as a finger can still be passed through it. On laying the mass open, it is found that a thick, somewhat flattened portion of the new growth projects into the lumen of the canal, and valve-like closes from above the contracted passage still remaining. The stomach, in the course of its greater curvature, is adherent to the diseased mass of the colon. The spleen (not enlarged) is also adherent. The other abdominal organs showed no marks of disease.

Dr. J. M. Barton exhibited a section under the microscope, which showed the neoplasm to be scirrhus.

REVIEW OF MEDICAL CHEMISTRY.

BY WM. H. GREENE, M.D.

EXAMINATION OF URINE.

MAX RÜBNER employs the following method for the detection of glucose: From ten to twenty cubic centimetres of the suspected fluid are treated with one and a half cubic centimetres of a strong solution of neutral lead acetate, and ammonia is added in sufficient quantity to form a permanent precipitate; the mixture is then warmed or allowed to stand for a time at the ordinary temperature. A rose or flesh coloration of the precipitate indicates the presence of glucose, although the latter may constitute as small a quantity as .02 per cent. of the solution. Lactose produces a similar result after long boiling. If ten cubic centimetres of a solution containing about .01 per cent. of glucose be boiled with the required quantity (one gramme) of pulverized lead acetate, and ammonia be added to the boiling liquid until a permanent precipitate is formed, the solution becomes yellowish or reddish, and a yellow precipitate separates. These reactions are said to be characteristic of glucose. When a solution containing at least .02 per cent. of lactose is treated as last described, a yellowish color appears and changes to brick-red; at the same time a partially crystalline cherry-red or copper-colored precipitate is formed. If an insufficient quantity of lead acetate be employed, the precipitate will be of a dirty-brown color.

In the application of the method to urine, the author recommends that the liquid be filtered from the precipitate first formed, and states that 0.1 per cent. of glucose, or 0.05 per cent. of lactose, can then be detected.

J. Seegen has reported a case of diabetes in which the urine contained levulose, the results of volumetric analysis, of fermentation, and of polarimetric examination corresponding so closely as to preclude the possibility of error.

Rautenberg has proposed that in the application of Liebig's volumetric method for the estimation of urea, the fifteen cubic centimetres of baryta mixture and urine (corresponding to ten cubic centimetres of urine) should be treated with an excess of pure calcium carbonate before titrating with the mercuric nitrate solution; sodium acid carbonate must then be substituted for sodium carbonate in determining the end of the reaction. Th. Pfeiffer has studied this process, and finds that it gives exact results, but that less mercuric nitrate is required than in Liebig's original method. A mercury solution of which each cubic centimetre corresponds to ten milligrammes of urea should contain only 60.186 grammes of the metal in a litre, and the degree of acidity of the liquid is not a matter of importance. According to Liebig, the too high results obtained in the analysis of solutions containing less than two per cent. of urea must be corrected by deduct-

ing from the number of cubic centimetres of mercuric nitrate used the product of the difference between this number and double the volume of the urea solution by .02. This coefficient is not, however, constant, and must be determined separately for every mercuric solution. For one of his solutions Th. Pfeiffer found that the dilution coefficient was .03. In the application of the method to human urine he recommends that the sodium chloride be previously precipitated by the addition of silver nitrate, a slight excess of which does not impair the accuracy of the results.

A. Villiers has made some experiments to determine the accuracy of the assertions of Bouchard and Pouchet that normal urine contains alkaloids. The results of the examination of his own urine and that of nine other persons lead to the conclusion that normal urine, voided during a condition of good health, does not contain alkaloids, but that the latter may appear during very slight indispositions, such as a light bronchitis or a feverish condition of the system. The same effects may be due to old lesions which are unnoticed and even forgotten by long habit; and Villiers suggests that the presence of alkaloids in the urine may at some time prove serviceable as a means of diagnosis in such cases. Alkaloids were found in the urine of patients suffering from measles, diphtheria, pneumonia, and phthisis, when no medicaments containing alkaloids had been administered.

For exact estimations of the total nitrogen in urine, E. Pflüger and K. Bohland recommend that five cubic centimetres of the urine be boiled with ten cubic centimetres of ordinary and ten of fuming sulphuric acid until the fluid is pale yellow in color. It is then diluted with water and distilled with eighty cubic centimetres of sodium hydrate solution of 1.3 specific gravity. The distillate is condensed in normal sulphuric acid, whose subsequent titration indicates the quantity of ammonia formed.

PTOMAINES IN PULMONARY DISEASES.

Villiers has extracted from the organs of two children who succumbed to bronchopneumonia after measles, a volatile fluid alkaloid. The organs were treated according to Stas's method, and the alkaloid was found in the lungs, the liver, and the kidneys. He suggests that the lesions discovered in these organs after pneumonia may be due to the presence of the alkaloid which he considers identical with that which he had previously obtained from the cadaver of a diphtheritic patient. It differed from the alkaloid found after death by cholera in its behavior towards reagents, in its feeble basic properties, and in its physiological action.

DETECTION OF ALKALOIDS IN ORGANIC SUBSTANCES.

Th. Chandler has published (*Zeitschrift für Physiolog. Chemie*, ix. 40) a new process for the detection of strychnine and other alkaloids in the tissues. The organs are finely chopped and mixed in a mortar with an equal weight of gypsum which has been previously dried at a temperature of 130° C. The mixture is dried on a water-bath at about 70° C., and then boiled with a solution of tartaric acid in ninety per cent. alcohol, the quantity of acid employed being equal to about one-hundredth the weight of the dry mixture. The residue left after the evaporation of the alcoholic extract is exhausted with boiling water; the filtered aqueous extract is evaporated to twenty or twenty-five cubic centimetres, rendered slightly alkaline with sodium hydrate, mixed with gypsum, dried in a desiccator, and the residue exhausted with chloroform. The chloroformic extract is evaporated to ten or fifteen cubic centimetres, and then mixed with an equal volume of a saturated ethereal solution of oxalic acid. In the course of twenty-four hours oxalates of the following alkaloids would separate from the liquid: strychnine, brucine, narceine, codeine, nicotine, conine, aconitine, hyoscyamine, veratrine, papaverine, thebaine. With the exception of the last two, of which traces remain in the solution, these oxalates are totally deposited. If the alkaloid be strychnine, the oxalate is collected on a filter, washed with a mixture of equal parts of chloroform and ether, dissolved in a little water, and decomposed with ammonia. If a quantitative estimation is desired, the weight of the dry strychnine must be increased by that which would remain in the aqueous solution which retains $\frac{1}{6667}$ of its weight. If the alkaloid be other than strychnine, it may be obtained pure by dissolving the oxalate in alcohol, precipitating the oxalic acid by the cautious addition of potassium hydrate and the excess of the latter by a

current of carbonic acid gas. The pure alkaloid then remains in alcoholic solution.

Pouchet has found that a pure culture-liquid of Koch's cholera microbe contains small quantities of a liquid alkaloid whose odor and poisonous effects appeared to be identical with those of the alkaloid he had previously isolated from the dejections of cholera patients. The confirmation of these results by those of experiments undertaken on a larger scale would be an indirect proof that Koch's bacillus is the veritable pathogenic factor of cholera.

E. Serrant advocates the use of orthoxyphenylsulphurous acid as an antiseptic, and proposes for it the name "aseptol." It is formed by the action of sulphuric acid on phenol, and is at ordinary temperatures a syrupy liquid, usually having a red color, soluble in all proportions of water. It solidifies at 8° C., and boils at 130°. Its antiseptic properties are claimed to be more active than those of phenol, and it is not very poisonous, so that it may be administered internally in tolerably large doses.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF THOMAS G. MORTON, M.D.,

One of the attending Surgeons to the Hospital.

NEW METHOD OF TREATING FRACTURE OF THE PATELLA.

A MAN about 50 years of age was brought before the class October 17, who twenty-four days previously had been admitted suffering with severe contusion of the right knee, and a transverse fracture of the patella just below the middle. The injury was caused by a fall while getting off from a street-car: the car being still moving, the patient stumbled, but retained his hold upon the car, which caused him to fall, and he was dragged a short distance upon his knees.

When he was admitted into the hospital on the 23d of September, he was confined in bed with a straight posterior splint under the knee-joint, and lead-water dressings were applied to check the effusion and cause its absorption. On the fifteenth day after his admission, all signs of inflammation having disappeared, the new apparatus was applied, which will be explained later. He has now had the instrument in place for nine days: it has accomplished its function of holding the fragments of bone in exact apposition during that time, as it does at present, and it has not excited any inflammation or signs of irritation.

The object sought to be attained in the treatment of fracture of the patella is to bring the fragments together as soon after the accident as possible, and retain them in that position until union takes place: if this is successfully accomplished, bony union may be confidently expected. In this case there was so much effusion that I even thought of resorting to aspiration of the joint; but finally the inflammation was controlled by evaporating lotions, compression, and rest. Two weeks passed before the apparatus was put on. I would prefer to apply it, as a rule, within a few days after the fracture, because the exudation which is thrown out between the fragments may prevent perfect apposition and thus hinder union. In order to get firm osseous union the bone must be adjusted as accurately and as early as possible.

Different expedients have been devised in treating fracture of the patella, all endeavoring to attain the desired end. One method in common use is a hinged posterior splint for the knee to rest upon, extending three-fourths up the thigh and about four-fifths down the leg. It has a screw by which the angle of the knee can be changed at pleasure; besides this it has on each side of the joint a screw-pin fastening both in the upper and lower segment. The bandage is to be fastened to these pins and passed above and below the patella, so as to draw the fragments close together and enclose the joint.

The effects of this pressure should not be ignored. The fragments are not very freely supplied with blood, and this pressure must interfere decidedly with the feeble circulation, and may cut it off entirely, but the bone requires a good circulation in order to get union. The major proportion of the forms of apparatus used in the treatment of fractured patella are open to this objection. This is the reason, in my opinion, why we have so many cases of fibrous union and so few of bony union. The disadvantage of fibrous union is that the gait is usually interfered with: lameness is the rule, its absence is exceptional. Sometimes the bandage is applied too tightly, and I have known it (though

not in my own practice) to cut down to and expose the tendon of the quadratus extensor muscle.

Here are Malgaigne's hooks, which Agnew's "Surgery" declares to be "infernal machines," though the author, I believe, states that he has never used them. I have applied them to proper cases for the last twelve years, and have never seen any bad results from their use. In one case, however, I can recall the fact that I had to take them off on account of continued effusion in the joint, which I had previously aspirated on several occasions; but this was not caused by the hooks, but due to the previous effusion and irritation resulting from the injury. Dr. Levis has separated the hooks into two lateral halves, with a view of obtaining more perfect apposition. I still use the original form, but for very fat persons I have had a pair made with the hooks extra long, in order to reach down to the patella when it is buried in fat.

In applying the hooks, they should be adjusted so as to bring the surfaces together, bone to bone. Then elevate the leg upon a splint, and envelop the joint in lead-water and laudanum. I have succeeded in getting bony union by this means in a number of cases of fracture of the patella, but I was still not quite satisfied, and so I devised this instrument. It is a slender drill in a movable handle (in fact, very much like Brainerd's drill). With this the fragments, after being placed in position, are transfixed from below upward, parallel with the axis of the limb, until the extremity emerges from the skin above the joint. The steel cap is then slipped on the end and fastened with a screw, so as to prevent the bones from becoming separated. The joint is then enveloped in an anodyne lotion, and elevated as before. The results have been excellent. There is no inflammatory reaction, there is not even redness, and not a drop of pus; the fragments are in perfect apposition, so that one can to-day scarcely, after careful examination, tell where the line of fracture was. The idea is that the increased supply of blood attracted towards the part by the irritation of the screw is of advantage in bringing about union. No bandages are required. His temperature has not been above normal. In order to insert this drill no anæsthetic was needed, as it gave very little pain. Of course the joint must be kept quiet and extended on a splint. There appears really to be no more risk with this instrument than with Malgaigne's hooks, and thus far I have been better pleased with it than with the hooks. It is a very much easier instrument to apply than any other form of apparatus.

COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

SERVICE OF OSCAR J. COSKERY, M.D.,

Professor of Surgery in the College of Physicians and Surgeons.

CASE OF HODGKIN'S DISEASE.

GENTLEMEN,—The patient before us comes from Pennsylvania with the following history. Aged 48, a mechanic, married, and with a good family history. Three ago, a lump made its appearance below each ear; soon afterwards a swelling came in each groin; a few months later, in the axilla; and, still later, below the first, in the neck. The patient only feels pain in any of the swellings when he exerts himself or indulges in stimulants. At times the growths are very much harder to the feel than they are at others. The physician in whose charge the patient has lately been, and who brings him to us, has used locally warmth and moisture, and internally the iodide of potassium and arsenic. Under this treatment the patient says that he has very much improved, and that the tumors have decreased in size. He does not say that he has "picked up flesh," or can do his work any better than he could a year ago, but that he feels generally better.

On examination, we find both sides of the neck swollen out by growths that can easily be grasped by the hand, are superficial, and are plainly enlarged glands. On each side the mass is as large as a turkey-egg. In each axilla is a mass of glands the size of a base-ball, freely movable, and pushing forward the pectoralis major muscle. In each inguinal region is a tumor formed of the upper range of lymphatic glands, irregularly knobbed, and measuring about two and one-half inches in every diameter. The enlargement on either side cannot positively be followed into the abdomen, on account of the size of this cavity; but, upon percussion, the splenic dulness is found to extend for five inches in the axillary line, and the liver-dulness to

below the costal border. While the patient is in seemingly good general health, it will be noticed that he is decidedly anæmic.

There can be very little doubt, from the history, the characteristics of the growths, their positions, and the age of the patient, that we have before us a case of what is now known as lymphosarcoma, lymphadenoma, or more familiarly as Hodgkin's disease,—for, although observed before his time, it was not until 1832 that attention was called to it as a special disease by Dr. Hodgkin. In this disease we find an increase in the general structure of the gland and a special deposit of fibroid structure. It is also much more common in males than in females, in the proportion of three to one. I have never myself seen it in the female sex.

In reference to the treatment, I have very little to say for this particular case. There is but one positive cure for the growths, and that is extirpation. On account of the number and extent of the enlargements and the almost certain implication of the internal organs, that radical measure is out of the question, and we must trust to internal medication. Billroth reports a case that was much improved by arsenic. Verneuil has strongly recommended phosphorus, and mercury and potassium iodide have been suggested. Two of these remedies have been used upon our patient, and with some success, as he says himself.

As to what will be the termination [the patient having been sent out], that will be the same as usual in these cases: death from asthenia. Most cases reported have died within the first two years; only one, that I am aware of, having lived over five years.

TRANSLATIONS.

THE ORIGIN OF CANCER IN CHRONIC INFLAMMATORY CONDITIONS OF THE MUCOUS MEMBRANES AND THE SKIN.—In the *Sammlung Klinischer Vorträge*, No. 257, Dr. K. Schuchardt presents an interesting contribution to the question of the relationship of cancer to chronic epithelial irritation, especially in the form of psoriasis of the mucous membrane, paraffin-itch, and senile seborrhœa, the microscopic details of each being carefully considered.

In the first part of the essay, after referring briefly to the history of two cases of sarcoma (of the orbit and of the head of the tibia) following traumatism, the author reports four cases of psoriasis of the mouth, and especially of the tongue, which terminated in carcinoma of the mucous membrane. In a syphilitic subject presenting the same condition, cancer did not appear. Three of the former cases were inveterate smokers. In another case an epithelial cancer developed from a psoriasis præputialis of six months' standing. The patient had a tight phimosis. Microscopically, the mucous membrane affected by psoriasis showed inflammatory infiltration of the superior layers of the corium, and in the epithelium numerous nuclei in a state of active proliferation; in the superficial cells, under the horny layer, elaidin was detected.

The second part of the paper reviews briefly the reported cases of chimney-sweeps' and coal-tar- and paraffin-workers' cancer of the scrotum, and reports six cases of paraffin-cancer (one of which had been previously communicated by Tillmann). Here also did the carcinomatous degeneration proceed from long-continued irritative conditions of the skin of the body or of the scrotum alone, in the form of acne, infiltrations, exanthems, scaly and scabby formations, warty excrescences, or seborrhœa, the essential phenomena being more rapid formation of the epidermis and increased activity of the sebaceous glands. In four cases it terminated in cancer of the scrotum, with enlargement of the inguinal glands and speedy return after operation. In two cases cancer attacked the upper extremities. In the last-mentioned, Schuchardt examined the portion of the skin affected by paraffin-dermatitis and found a typical growth of the lowest epidermic layers, at the basis of warty formations epithelial nests (*schichtungs-kugeln*), in the neighborhood of which the cells were infiltrated with elaidin, dense crowding of the hair-sheaths with non-nucleated scales, and small-celled infiltration of the cutis. As an especially predisposing condition to cancer of the face was considered seborrhœa senilis. This peculiar affection, as is well known, is characterized by the appearance of usually multiple, circumscribed, prominent, yellow or brown, fatty, scaly accumulations. It especially

affects the skin of the face, but is also encountered on the thorax and neck, rarely on the extremities; almost exclusively observed in old people of the lower class. Microscopic examination discovered nothing abnormal in the sebaceous glands, while a very significant change was detected in the superior layers of the epidermis and in the hair-sheaths, terminating in partial corneous desquamation. The hair-follicles were often found entirely filled up with newly-formed epidermic scales. Here and there it was demonstrated that the secretion might have been retained, for sometimes at the root of the hair large or small drops of fat were visible underneath the scaly accumulation. The same granular fatty deposit was also found between the corneous scales themselves, pressing apart the lamellæ of epidermic growth; finally gaining the surface, it gave the fatty character to the scales.

Especially noticeable was also a marked inflammatory infiltration in the superior layers of the corium, especially in the papillæ. Apparently, want of cleanliness, besides advanced age, exerts an influence upon the origin of this disease. This accords with the predominance of the affection in subjects from the lower walks of life, among whom personal cleanliness is wanting. It is in this fact that Volkmann especially sees the explanation of the tendency to cancer of the face, and his experience harmonizes with this view, for at the most only two per cent. of all cases of cancer of the face occurred in the higher classes, who pay more diligent attention to cleanliness. After communicating a few characteristic examples of facial cancer arising from senile seborrhœa (*seborrhagische Carcinome*), Schuchardt expresses the opinion that at an earlier period of life acne sebacea and xeroderma pigmentosum may also afford occasion for the development of carcinoma.

A short reference to the prophylaxis concludes the essay. With regard to psoriasis of the tongue and mouth, the application of Pacquelin's cautery is especially recommended.—From Kramer's review in *Centralblatt für Chirurgie*, No. 40.

Chorea.—M. Joffroy treats chorea successfully with chloral hydrate and the wet sheet. The dose of chloral, for patients over ten years of age, would be one drachm, in three doses, given after meals; fifteen grains about seven in the morning, fifteen at noon, and thirty at about six o'clock in the evening. In children of six or seven years the dose must be reduced; but enough should be given to induce sleep fifteen minutes after the administration of each dose. If the choreic movements are very decided, it is recommended to wrap the child in a wet sheet for half an hour night and morning, and afterwards to have the body well rubbed with the palm of the hand. Eighteen cases reported by M. Sarie show that this treatment is of decided value. It is claimed that it reduces not only the duration but also the intensity of the disease. In the majority of cases it terminates in four to six weeks.

Periodical Amnesia and Hysteria Major in Man.—In the *Archives de Neurologie* for September, Dr. Jules Voisin reports a case of convulsive hysteria in a man 21 years of age, with doubling of the personality, in which the hysterical crises were checked by pressure upon the tendons, notably the tendo Achillis. The patient offers one of those rare and curious conditions in which the cerebral hemispheres appear to act alternately and at considerable intervals, the subject living in two states of existence entirely distinct from each other both in mental accomplishments and physical conditions. The patient had attacks of pulmonary congestion with hæmoptysis without phthisis, but evidently of neurotic origin. Some interesting observations were made as to the effects of hypnotism in provoking aphasia and hemi-catalepsy.

Copaiba Suppositories for Vaginitis.—Inflammation of the vagina, whether virulent or not, has been successfully treated by Prof. Ball with suppositories containing five grammes of copaiba and cacao-butter and five centigrammes of extract of opium, given every second day. The suppositories remain about twelve hours. The patients recover in about twenty days.—*Bull. Gén. de Thérapeutique.*

Cocaine Hydrochlorate in Sea-Sickness.—In a brief communication to the *Berliner Klinische Wochenschrift*, No. 43, Dr. W. Otto states that the use of cocaine, in doses by the mouth of gr. ¼ to ⅓, in sea-sickness will rapidly relieve vomiting and nausea and produce sleep.

EDITORIAL.

BILIOUSNESS AND BILIOUS HEADACHE.

A NEW explanation for the familiar symptoms attending the condition known as biliousness has been offered by recent investigations in biological chemistry. Leaving out of consideration cases of simple indigestion, *embarras gastrique*, constipation, and acid conditions of the contents of the lower bowel, which in popular language are all styled "biliousness," and those nerve-storms which, taking the form of migraine, are often mistaken for bilious attacks, there yet remain many cases which are fairly attributable to some disorder of the hepatic function. Harley, for the sake of perspicuity, divides biliousness into three forms: acute biliousness, due to hypersecretion of bile; subacute biliousness, due to diminished secretion of bile; and chronic biliousness, due to imperfect secretion both as regards the quantity and quality of the bile, restricting the terms torpid or sluggish liver to the latter form. Fothergill attributes it to the effects of excess of nitrogenous food upon certain individuals, and declares, even more perspicuously, "that in all cases there is an excess of bile."* The nexus between deficient or disordered hepatic secretion, which, strictly speaking, constitutes biliousness, and the attendant clinical phenomena, seems likely to receive its true explanation from modern physiological research. That it is a form of toxæmia had already been recognized, and also that in many cases it is due to failure on the part of the liver in removing excrementitious substances from the circulating fluid. There is strong probability, however, that in other cases the liver may be only indirectly at fault. It is an important function of the bile to prevent fermentation of the contents of the intestines. Should this action be wanting, and putrefactive changes take place, all the conditions seem favorable for the development of ptomaines, which, if absorbed into the blood, may produce symptoms of acute poisoning. Lauder Brunton, in a most interesting and suggestive paper "On Poisons formed from Food, and their Relations to Biliousness and Diarrhœa,"† refers to a case reported by Lépine and Mollière, in which symptoms of acute atropine poisoning occurred, with death on the second day, in a man suffering with intestinal constriction. A peculiarly offensive fæcal mass was found in the bowel, which was believed to be the origin of the poison.

It is not only in diseased conditions that such alkaloids are formed. Bouchard extracted from human fæces a substance which, injected into rabbits, produced death by violent convulsions. He thinks that absorption may occur under certain conditions in man, and he proposes to name this condition "stercoræmia," analogous to "uræmia." Since the weight of evidence is opposed to the view that uræmia is caused by the presence of urates or urea in the blood, and as the title stercoræmia would imply the relationship of stercorin to the morbid state, one term seems at least as objectionable as the other, as implying definite ideas of pathology which have not as yet been demonstrated to be true.

Bilious headache, formerly supposed to be due to viscidity of the bile, and associated jaundice attended by more or less catarrhal swelling of the bile-ducts, seem susceptible of another explanation. The action of certain poisons may produce sim-

* Practitioner's Hand-Book of Treatment. Philadelphia, 1877, p. 37.

† Practitioner (September and October).

ilar conditions. Schmiedeberg noticed that toluylendiamine, a substance belonging to the aromatic series, produces jaundice; and Stadelmann, by whom the effects of this drug have been further investigated, found that the first stage of its action corresponded to the condition of biliousness, with excess of bile in the stools. Brunton believes that the second stage may correspond to the so-called catarrhal jaundice, especially when occurring in epidemics; though it is also possible that the usual explanation of the causation of catarrhal jaundice may be in many cases the correct one. A substance obtained from lupin-seeds has such marked power of causing jaundice that the name "ictogen" has been proposed for it by Kuhn.

Although these compounds have not yet been detected in the body or among the products of albuminous decomposition, yet similar ones, notably carbolic acid, have been found, even in the urine of healthy men. The object of immediate treatment, therefore, would be to eliminate from the intestinal tract and circulating fluids all possible sources of auto-infection, and in general to guard as much as possible against the possibility of poisoning by the products of putrefaction of the albuminous contents of the intestine. Cases of egg-poisoning and the toxic effects following the ingestion of canned beef, ice-cream, cream puffs, etc., are apposite, but cannot be further considered in this place.

THE SANITARY EXAMINATION OF POTABLE WATER.

WHILE the determination whether a sample of water does or does not contain poisonous substances of a mineral nature is not a matter of difficulty, the classification of a water as safe, suspicious, or bad, so far as its organic constituents are concerned, can, in the present state of science, only be inferred from the results of examination by several methods. Unfortunately, these methods require great nicety of manipulation and considerable skill, so that they can only be undertaken in a well-appointed laboratory.

The facts to which most importance seems to be attached are—the quantities of organic carbon and nitrogen present in the dry residue of the water, the proportion of ammonia that can be obtained from the water, the amount of potassium permanganate required to oxidize the organic matter, and the quantities of nitrites and nitrates present.

Recent reports on water-analysis point to the mere presence of nitrites as particularly suspicious; and, although a physician can rarely undertake a thorough analysis of water, there are methods by which the presence of nitrites may be quickly detected with certainty. One of these methods consists in adding to about four fluidounces of the water to be examined a few drops of pure hydrochloric acid, then about half a fluidrachm of a solution of sulphanilic acid and the same quantity of a solution of hydrochlorate of naphthylamine. The presence of nitrites is betrayed by a rosy or red color, which is developed in about twenty minutes, and the reaction will detect one part of nitrous acid in more than a thousand million parts of water. The other test is metaphenylene diamine, which produces a yellow color when added to water containing nitrites and acidulated with sulphuric acid. The first test is the more satisfactory; but it is important that the acids used in each be perfectly pure.

DR. KIJONORI KASHIMURA, Professor of the Practice of Medicine in the University of Tokio, passed through this city last week *en route* to San Francisco and Japan. He visited Pennsylvania Hospital, Jefferson College, and other places of medical interest. Prof. Kashimura founded the *Tokio Medical Journal*, and edited it for a number of years. We wish him a safe voyage.

FREE ADVICE FOR THE INSANE POOR.

THE Pennsylvania Hospital (commencing upon the 2d instant) has now a regular dispensary service for mental diseases, conducted at the Hospital for the Sick, at Spruce and Eighth Streets. On Mondays and Fridays, at 3 P.M., physicians of the Department for the Insane are regularly in attendance to give advice and medical treatment, especially in order to encourage proper treatment in the early stages. This work is of an experimental nature, and if found useful will be continued; otherwise it will be abandoned after a fair trial. We hope that it will be a permanent feature of this great charity, as, when its advantages become better known and appreciated, it will be able to render inestimable service to the insane poor.

THE Executive Committee of the International Medical Congress held a meeting at the Murray Hill Hotel, New York City, on Wednesday, the 18th instant, at which Dr. Henry H. Smith, of Philadelphia, presided. A fair attendance was had, though many of those living at a distance were absent. Among those present were Drs. Austin Flint, N. S. Davis, F. S. Dennis, and R. J. Dunglison. Dr. Dunglison is the chairman of the Finance Committee (an eminently fit nomination, which he has finally decided to accept). After filling vacancies in the *personnel* of the Sections, and transacting some private business, the committee adjourned, to meet at the call of the chairman.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The Thirteenth Annual Meeting will be held at Washington, D.C., December 8–11, 1885. Transportation at reduced rates can be obtained by application to the local committee of arrangements, Smith Townsend, M.D., Chairman, and J. C. McGinn, Secretary. The meeting promises to be largely attended.

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

PROF. TERRILLON, in the course of some practical remarks recently at the Salpêtrière on "Ascites with Abdominal Tumors," said that ascites, or liquid in the abdominal cavity, may be produced in three different conditions: the circulation may be *embarrassed* locally, as in some varieties of hepatic cirrhosis, or indirectly, as in heart-troubles; or the peritoneum itself may be inflamed or irritated, as when associated with abdominal tumors. In the last few years points of differential diagnosis have been elucidated. If the ascites be from obstructed circulation, the liquid will be a limpid fluid, resembling water, perhaps slightly colored, containing a little albumen, but no fibrin, and giving no sediment; containing rarely a few red globules; more often a few small white globules. If the ascites be from peritoneal inflammation, the liquid will be thinner, but never transparent, always cloudy, looking like buttermilk and smelling like decayed cheese. There is a great deal of albumen in this liquid, and of red cells and large white globules, and it deposits a thick sediment. If the effusion be from simple serous irritation, the liquid will be albuminous, rather clear, and often colored like bile. In the sediment will be found elements of great importance. Besides large white globules full of fatty granulations, large irregular cells may be seen, having a central nucleus surrounded by a quantity of granulations. The presence of these cells is usually taken as the sign of a malignant growth being present.

Besides these differential characters, M. Méhu has shown that these liquids do not give the same weight of residue. Twenty per thousand is the rate in the first kind, and forty in the second; in that accompanying ovarian cysts the figure goes up to seventy-five or eighty. One word more on the examination of the liquid: we should not at once conclude on some form of cancer if blood be in it, for we often find it in the simplest forms of irritation.

Ascites rarely accompanies simple ovarian tumors. On the other hand, it is very frequent in external papilloma which irritate the peritoneum. It is also almost always found with malignant tumors, such as sarcoma and cancer of the ovaries, intestines, etc. As a general law, it may be said that *there is no connection between the volume of a tumor and the quantity of the ascites.* One of our patients had sixteen quarts of liquid with a tumor not as large as your closed fist. The books tell of the usual symptoms by which we recognize ascites,—the large belly, the sensation of wave-motion from side to side, etc. There are, however, two modes of diagnosis

that are not much written about: first, always look for a marked dulness in the lumbar region; second, the vaginal cul-de-sac affords a good chance to detect fluid by making a vaginal or rectal examination; the liquid collects in the recto-vesical pouch and may be detected by the finger. This is, indeed, the only way to decide the diagnosis between ascites and an ovarian cyst.

Having detected the ascites, we ask what is the cause of it? There are only three ways to find out. First, examine the abdomen; then puncture, and examine the fluid; finally, make an exploratory incision. If the patient have a great deal of liquid and a small tumor, the physical examination will not reveal much. If there be only a little liquid, there are a few signs that may help; but they are not very sure. Sometimes it is possible to depress the abdominal walls and reach the tumor; there may be a real *ballottement;* and, finally, we may by vaginal examination place the tumor in communication with the abdominal walls, so that we can feel it. These means are not many nor very efficient. In making a puncture with the aspirator, we observe three rules: 1st, antisepsis of the strictest kind for the trocar and the skin of the patient; 2d, open the abdomen in the median line, to prevent wounding any large vessel; 3d, the depth to which the instrument is passed must not be great. He did not insist so much upon the second, but never neglected the first and third rules. Coming now to the third mode of diagnosis, the exploratory incision, his advice was to make an exploratory incision; then, if the operation is possible, do it; if not, close up the abdominal cavity. The question will arise about drainage. There are two opinions here; some say drain, others not. He believed both were right, and we must act according to the case. But in ascites it is hardly possible that the peritoneum will absorb a mass of liquid after the traumatism has been made: so that drainage will be necessary very often, either abdominal or vaginal.

Before leaving the Italian Medical Association meeting, held at Perugia, mention should be made of the remarkable specimens of preserved cadavers that were presented by Dr. Comi, of Rome. An entire fœtus was shown, with heads, hands, and other parts of adults that had been preserved with their natural form, color, and consistence for years,—one bust of a man since 1879.

Dr. Comi gave the following formulæ:

1. *To obtain the hardness of stone in organic bodies.*—For this purpose he mixes linseed oil and bichloride of mercury so that it will form a mass the thickness of mortar. In this he puts the parts for a number of months, varying according to the size. When they get hard enough, he washes them with turpentine and then dries in the air; afterwards they are polished with agate-stones. If the part is hollow, he fills it with a cement of plaster and bichloride of mercury, equal parts. Artificial eyes must be put in the orbits.

2. *To preserve organic bodies in a flexible state.*—All that is required is to steep them in the purest honey, the finest and clearest that can be found. The cephalic, thoracic, and abdominal cavities must be filled with tannin. The result obtained here is due to a sort of fermentation, alcoholic in its nature, that keeps the parts for a long time; afterwards they harden.

Prof. Germain Sée spoke on "Obesity" recently at the Academy. He does not believe in the Banting system; he thinks that nitrogenized substances, taken in excess, produce a certain quantity of fat. Besides, the works of Voigt, Rubner, and others prove that fat is a substance of great importance in the economy, and we are not justified in depriving our patients of it. He recommends, therefore, to our fat friends that they take fatty food, but to a less extent than the others: taking sixty to eighty grammes, in place of the one hundred and ten to one hundred and twenty that a man in good health would take. To this he adds gelatinous substances and peptones. In regard to drink, most doctors advise an almost complete abstention; but Dr. Sée does not believe in this as far as it relates to non-alcoholic drinks, such as tea, light coffee, etc. Béclard has shown that liquids do not remain in the stomach, but pass at once to the intestines. They are thus of no disadvantage to the difficult digestion of fat people, which arises from the extra coat of fat they have on their hearts. Water then, passing, as it does to be digested, into the intestine, does good, as it will increase the amount of urea eliminated, and act mechanically by washing out the body, and do good by its action on combustion in general. Sweating is only another way of suppressing water, and is of no more value in treatment of obesity. As to medication, three sorts are adopted,—iodine, the alkalies, and purgatives. Iodine acts well and makes the patients much thinner, but it is apt to cause iodism in fat people, so they ought to receive a constitutional treatment first. Alkalies are of but little value. Purgatives are useful, as they sweep very quickly out of the intestines all alimentary residue. The natural waters, as Marienbad, Carlsbad, and Châtel-Guyon, in France, are the best form in which to give cathartics.

The examination for the places annually made vacant of interne and externe in the Paris hospitals took place last week. First of all came up the women-question, the authorities having decided that ladies may try for both the interne and externe places; but the

opposition is very great. Just before the opening the male students began crying out, "No women!" "No petticoats!" Miss Blanche Edwards and Miss Plunkett sat quietly and appeared by no means disconcerted. The students filled up the time by singing in chorus to a popular air "Bamboula,"—a nickname they have given to a colored lady who is following the same curriculum as themselves, but who was not present. The authorities are firm, however, and ladies who wish to try for house-surgeon can do so: they will be subjected to the same tests as the men. A fair field and no favor is offered to all aspirants. The opening of the interne examination was the signal for another outbreak. The questions given out were the "Relations of the Stomach and Duodenum," and the "Pathological Anatomy, Symptoms, and Diagnosis of Cholera." On this a rumor went round that these questions were known to a number of the students before they were declared, and that they had been divulged by Dr. Gouguenheim, one of the jury, to some of his hospital-staff before the contest. On this, a most disorderly scene took place, the students rising *en masse* and calling for the resignation of the doctor who had told the secrets of the question-box. The meeting was adjourned at once, and on the committee making inquiry, it seems they found out that an interne in Dr. Gouguenheim's service had by some means got hold of the questions and had communicated them to others. Dr. G. protested that he had said nothing; but the authorities cancelled the first selection and nominated a fresh jury, who met yesterday, gave a new set of questions, and proceeded to a new examination.

"*Hic finis fandi.*" Here we may as well make an end of the Ferran system of inoculation. Although the report of the Madrid Royal Commission is not yet published, the most important of its conclusions are known. They are as follows. 1. The Commission affirms that Ferran's system cannot be considered as inoffensive. 2. That the liquid employed is not properly attenuated. 3. That it is impossible to form an opinion of its results from the different manner of cultivating it employed. 4. That the inoculated individual can transmit the cholera. 5. That the symptoms presented in the vaccinated cannot be considered as characteristic symptoms of experimental cholera. 6. That the inoculated person presents a special tendency to catch all sorts of diseases. 7. *That the inoculation gives no sort of immunity against the cholera.* These important statements, coming from the most eminent doctors of Madrid, show how right they were here in taking certain precautions from the first against Dr. Ferran and his system. According to a letter just received from Spain, Ferran went lately to a small place called Cambils, where up to then there had been no cholera. Soon after the inoculations, eleven deaths took place; five of them were of those who had been inoculated. Besides this, a large number of accidents from gangrene arose, and no less than eleven amputations of the arm took place! This closes the scene.

According to a St. Petersburg paper, the celebrated Russian traveller Dr. Fodtschenco recently discovered in Turkestan a plant which is said to be an excellent specific against cholera and typhus. It is used by the natives of Central Asia against all kinds of maladies, and every effort has been made to keep its properties from the knowledge of Europeans. The plant, which is named "Ferula Sumbul," has been acclimatized in the Moscow Botanical Garden, and the justly great name of Fodtschenco deserves this notice of its merits.

Dr. Audhoui recommends the following laxative powder in cases of constipation from the use of rich food:

Powdered orange-leaves, 6 parts;
" aniseed,
" sugar, of each, 2 parts;
" senna-leaves, 8 parts;
" magnesia, 2 parts;
Essence of mint, 5 drops. M.

S.—One to two tablespoonfuls to be taken in a little water.

Hæmostatic Pills (Dr. Huchard's).—

℞ Ergotin.,
Quininæ sulphatis, āā 2 grammes;
Digitalis,
Ext. hyoscyami, āā 20 centigrammes.
M. et fiat pil. xx.
S. Give five to ten daily, in any hemorrhage.

In answer to some inquiries, permit me to state that there is only one medical school in Paris, the Faculty of Medicine, and that the system of medical education adopted here is quite different from that followed in the United States and elsewhere. The professors at the school do not deliver a regular course of lectures, but take up a branch of medicine or surgery and follow it as far as possible all through from beginning to end. Prof. Sappey, for instance, will lecture all winter on a part of the lymphatic system, and the other lectures at the school itself are all lectures on special subjects. Physiology is about the only subject gone over in the year. No chemistry is taught in the laboratories. Anatomy is taught in the new dissection-rooms, and the other subjects in the hospitals. The lectures in the college-building are not much attended. Of some five thousand students registered, not two hundred attend the lectures with any regularity. Yet the instruction

given in Paris is most complete. The best medical and surgical instruction is that of the hospitals, where some twelve to fifteen clinical lectures are given daily to any one who chooses to come in. No student is compelled to attend any one course of lectures, but, on examination before the faculty, will be taken on any portion of the branch in question. Medical lectures are given at the Collége de France, by Prof. Ranvier on Histology, and by Prof. Brown-Séquard on Nervous Diseases; but this is not a medical college. Admission to listen to the debates at the many medical, surgical, and other societies is free.

PARIS, October 30, 1885.

I hasten to send, with some detail, an account of the important communication that M. Pasteur made to the Académie de Médecine on the 27th instant, as the newspapers mostly made a muddle of it. The scientific world has long been aware that Professor Pasteur was in search of a method to cure hydrophobia, and knew that his trials on dogs had been successful. M. Pasteur now comes to show his attempts on human beings. He said,—

"The prophylaxis of rabies which I have attempted to show in former communications was a real progress, but it was not entirely satisfactory, as out of twenty dogs treated I could only guarantee fifteen; but now, after a great many attempts, I have a method that is prompt and practical, and in which I have confidence in its application to all animals and to man himself. The method stands on the following facts. The inoculation of a rabbit under the dura mater (by trepanning) with a solution of the spinal marrow of a dog which has hydrophobia will always give the disease to the rabbit after an incubation of about fifteen days. Now, if the virus of this first rabbit is passed on to a second rabbit, and then to a third, and so on, there will be manifested a tendency to a diminution in the time of incubation. After twenty to twenty-five passages from rabbit to rabbit, one comes to a duration of incubation of eight days, then to one of *seven days*, and this one will remain with great regularity during a series of passages as high as ninety. This is the *practical* point of the system, as by this means one can have always on hand a virus that is constant and of perfect purity. The spinal marrow of these rabbits (which die of rabies) is all virulent and constant in its virulence. If one now detaches from these marrows some pieces a few centimetres long and then suspends them in pure air, the virulence will gradually disappear. This is the *scientific* point in the method. These facts having been established, here is the means to make a dog quite proof against hydrophobia. In a series of bottles (in which the air is kept dry with some fragments of potash in them) suspend a small piece of marrow taken from a rabbit that has died after having had hydrophobia that developed after seven days. Do this every day. Then inoculate the dog, also every day, with a syringeful of a sterilized soup in which you have mixed a small fragment of one of the marrows that are drying. You commence with a marrow that is some days old, in order not to have it too virulent. Then on the following days operate with more recent marrows, separated by an interval of two days, and so on to the last, when you use a very virulent one of the day before. The dog will then be proof against hydrophobia. You can inoculate him with the most virulent matter and he will not take hydrophobia. With this method I have protected fifty dogs, of all ages and races, without a single failure.

"On the 6th of July last I was waited upon by three persons who had just arrived from Alsace. They were Theodore Vone, a grocer, of Meissengott, who had been bitten by a mad dog on the 4th of July. His arm was much bruised, but he assured me that his clothing was not pierced by the dog's teeth, so I sent him away. The other persons were Joseph Meister and his mother. This little boy (nine years of age) had been bitten by the same dog in a very serious way, as he had wounds on his hands, his thigh, and on his legs (fourteen in all), some of them so deep that he could hardly walk. Most of the wounds had been cauterized by Dr. Weber, with carbolic-acid solution, at Villé the same evening at eight o'clock. The dog was killed by his master, and an autopsy made. His stomach was full of hay, straw, and fragments of wood, so that he was certainly mad. The boy was taken from under him, covered with blood and foam from the dog's saliva. On consultation with Professors Vulpian and Grancher, they said no doubt that the boy would have hydrophobia. Spite of all, I hesitated to subject him to the same treatment that had so well succeeded in the dogs. Afterwards, however, in presence of the two professors named, I inoculated little Meister in a fold of the skin in the right hypochondriac region. During a space of ten days the lad had thirteen inoculations. The first had been kept fourteen days, the second twelve, until at last I injected marrow from the mad animal on the same day that the creature died. Thus in the last stage of the experiment I had inoculated him with rabid virus of the most malignant type. Three months and three weeks have passed since, and the boy is quite well."

M. Pasteur, in concluding, gave the outlines of another case that he has now on hand, of a boy of fifteen who was bitten in both hands about a fortnight since. He hoped to save this patient by the same means.

M. Pasteur, in promising the Academy of Medicine to communicate to them as soon as possible the result of the case he has in hand, said further, in regard to his method, that he did not know what interpretation to give to his discovery. One mode of explanation,

that seemed strange at first sight, was that of the fact that many microbes develop a substance in themselves that will destroy them. This is so in the "aspergillus niger." It will develop a substance that is dangerous to it, if there is no salt of iron in the nutritive liquid. M. Pasteur then asks the question, "Can what constitutes the substance that causes hydrophobia consist of two distinct parts, one of which kills, as it were, the other when it is in a certain proportion?"

Long and sustained applause greeted the professor on the termination of his paper, but several members rose at once to contest its points. The President, M. Bergeron, however, put off the discussion until a future meeting. M. Guérin, however, got in a word of protest. He wished to remark that it seemed to him a sort of artificial or theoretical hydrophobia that M. Pasteur spoke of and treated, and not the real classic disease. He feared the remedy which was good in theory was perhaps not practicable for *real clinical rabies*. Nothing told him that the carbolic acid used did not save the boy.

In the Academy of Sciences Professor Vulpian spoke highly of the great discovery of M. Pasteur, and said it was a credit to France and to humanity, and that he was sure it would prevent the dreadful disease in man.

THOMAS LINN, M.D.

PROCEEDINGS OF SOCIETIES.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, NOVEMBER 5, 1885.

The President, B. F. BAER, M.D., in the chair.

LYMPHATIC LEUKÆMIA IN CHILDHOOD. BY JOHN M. KEATING, M.D.

THE short paper which by invitation I propose to read to you this evening will, I am sure, prove of interest on account of the clinical rarity of the disease and the infrequency with which we meet it in current literature. To make the subject more interesting and more lucid, at the risk of recalling to your memory matters already familiar, I will premise with a few remarks on the blood in health in children, and briefly with its diseases.

There is a uniformity of composition of healthy blood which is curious. This is brought about by that equilibrium which is so striking in textures regulated by the production and waste.

The blood-corpuscles which we are called upon to study are: 1st, the *red*, of which there are floating in the plasma about five million to the cubic millimetre. These are about $\frac{1}{3200}$ of an inch in diameter. 2d, the *white*, of a diameter of $\frac{1}{2500}$ of an inch, having the proportion of one to every three hundred or five hundred red. 3d, the nucleated red, found in the fœtus and infant, and disappearing about the third or fourth year of life. These may contain one or more nuclei, in some instances protruding from the cell. They measure from $\frac{1}{1400}$ to $\frac{1}{2000}$ of an inch. 4th, the *hæmatoblasts* of Hayem: "small, discoid, colorless, corpuscular, normal constituents of healthy blood; in drawn blood they aggregate in clumps known as Schultze's granule-masses."

As to the origin of the red corpuscles, I will quote: "They are developed from colorless corpuscles, the lymph-cells, or leucocytes. The nucleated corpuscles of the embryo also aid in the development. These nucleated cells disappear early in childhood, and are then found only in the red marrow." It is Osler's opinion that "they apparently originate from colorless marrow-cells, which gradually become more homogeneous, and hæmoglobin develops in the protoplasm, the nucleus degenerates and disappears, when the cell has the appearance of an ordinary red disc." Possibly these nucleated cells may give birth to red cells by the process of budding. The relation of the cytogenetic organs to blood-formation has always been somewhat debatable ground: the present state of our knowledge may be formulated about as follows: "The spleen certainly takes part in the development of colorless corpuscles, but its participation in red blood-formation is more doubtful; though the opinion prevails widely that the spleen is one of the important organs in the formation of red corpuscles. The evidence for this belief is of an exceedingly scanty nature.

"The lymphatic glands and adenoid tissues in other regions are the seat of constant production of colorless corpuscles, but of their relation to the red corpuscles there is the same lack of information as in the spleen."

Neumann and Bizzarzera pointed out the fact that the red marrow appears to be the seat of blood-formation. In the adult it is the only region in which embryonic or nucleated red cells are found. In the young the marrow fills the long bones.

It is Osler's opinion—and I have quoted from his recent admirable articles on this subject—that the evidence of the development of red corpuscles in the marrow rests upon the constant presence of nucleated cells infiltrated with hæmoglobin, and of their fusion. In excessive hemorrhage, natural or induced, it appears to undergo active proliferation, and it is an interesting fact to notice the marvellous rapidity with which the red corpuscles are reproduced after a hemorrhage. The amount of hæmoglobin in healthy blood, according to Preyer, is 13.45 grammes to 100. This relation is important for us to bear in mind, as it proves an index to treat-

ment. The color-test being used, I feel certain that before long it will be a matter of more than ordinary interest to the general practitioner when the means of applying the color-test shall be generally adapted, as has been done already, to daily practice.

In the new-born the blood is said to amount to one-tenth part by weight of the body; in the adult, one-twelfth to one-fourteenth. I may also note that it has been shown by Neumann that the liver in the embryo may be the seat of the formation of corpuscles, though in the adult it is the seat of their destruction.

Let us now take up the subject of anæmia in children. Were I to attempt to do justice to this condition, it would take far more time than your patience would allow. We will omit that caused by hemorrhage, by toxic agents, by mineral poisons, by miasm, by syphilis, in which we have an increase in the watery elements and a diminution in the albuminous, and consider that dependent upon disorder of the blood-making organs themselves. And here we meet with a most difficult problem. By the blood-making organs we understand the spleen, the lymphatic tissues, and the bone-marrow, remembering, of course, that some of these tissues have also to do with blood-destruction. We, however, definitely know that an increase in the cytogenetic tissues is associated with disturbances in blood-formation. The organ undergoes a hyperplasia, particularly of its fibrous constituent, and the marrow of bone changes from normal appearance to one like spleen-pulp. The blood of all patients suffering from anæmia presents a reduction in the number of red corpuscles. This is true no matter whether the seat of the trouble is located in the spleen, in the marrow of bone, or in the general lymph-glands. The white cells may or may not be increased. The clinical features of a case of anæmia will be strikingly alike, let the cause be in any one of the blood-making organs. All the more important symptoms will be present. To quote once more, such common features would be "the progressive anæmia with its group of circulatory symptoms, the irregular febrile reaction, essential fever of anæmia, the absence of marked emaciation, the tendency to effusions of serum, the progressive debility, the recurrence of hemorrhages gastric and intestinal, gastric and intestinal disturbances, and the resistance to treatment."

These affections that have so many symptoms in common are grouped as distinct diseases under the following headings: leukæmia, Hodgkin's disease (anæmia lymphatica), splenic anæmia, and idiopathic anæmia.

Leukæmia signifies a hyperplasia of the blood-making organs, with anæmia and an increase in the colorless corpuscles. Of this form we have three varieties,—the splenic, lymphatic, and medullary. Leukæmia is present at all ages, the youngest case recorded by Osler being an infant of eight months. The chief symptoms are insidious onset, anæmic appearance, bleeding at the nose or other hemorrhages, frequent diarrhœa or other gastro-intestinal disturbance. The spleen is enlarged, gradually increasing in size from the onset, and finally it may interfere with the circulation and cause difficulty of breathing by pressure. Late in the disease the liver is also enlarged. The lymph-glands in most cases are affected, and sometimes slightly enlarged. The tonsils and follicles of the pharynx are usually enlarged. The lymph-glands of the intestines and of the peritoneum are always enlarged. Fever is present, and increases as the case progresses, and is usually of the remittent type. But the most important aid to differential diagnosis is the microscopical examination of the blood. This I give in detail in the case that forms the basis of this paper, which I will now relate. I was called in consultation by Dr. I. W. Gadd, of this city, to see the child with him the latter part of last month, and the following notes were given by Dr. Gadd:

Mamie McC., aged $4\frac{5}{12}$ years, had measles when about two years old, from which she recovered without complication or sequelæ. About August, 1884, the tissue surrounding the eye became much inflamed and swollen. The swelling increased so much that the eyelid could not be opened for several days. After continued poulticing, an abscess formed and broke, discharging a quantity of pus, and continued to do so for a considerable time, but finally healed up with small scar. The child never complained, yet was pale, and did not want to play as other children did. I believe this was more due to her disposition than to the effect of any disease.

About midsummer there appeared a rash all over her body, very thick, and resembling the eruption of measles. As it matured, it was crowned by small white caps or heads. The epiderm soon came off in large patches. The child had no fever. As the eruption faded, the mother observed purplish spots, like bruises, making their appearance. These were considered by the parents to be bruises due to falls. No attention was paid to her condition until September 28, when I was called in the evening to arrest an epistaxis which had existed most of the day. I found the child lying on a sofa, though able to sit up, with blood slowly trickling from the nose. Each nostril contained a large clot. The child appeared very anæmic, with slight fever, yet did not complain of anything except weakness. The mother stated that the appetite had been very poor for some time past. The bleeding from the nose was very easily arrested by removing the clots and packing with a strip of lint in each nostril. I also gave the following internally:

℞ Acid. gallic., gr. xxx ;
Acid. sulph. dil., ℥xl ;
Ext. ergot. fl., ℥xxx ;
Syrupi, fℨj ;
Aquæ, q. s. ad fℨij. M.
Sig.—A teaspoonful in water every hour.

Also ordering her as much milk as she cared to take, with the precaution that she should sip it slowly.

Tuesday morning I saw her, and found her in the same condition, except that the epistaxis had been arrested. I thought it best not to remove the lint packing. It now being daylight, her mother called my attention to the bruise-like spots over her body. These were in size from that of a two-cent piece to that of a fifty-cent piece, and two of them, situated one over each trochanter, were as large as silver dollars. With the exception of these two, they were all, I believe, situated over the soft parts, such as over the belly of a muscle, and varying in color according to age, from a bluish black to a greenish yellow. She still had some fever, and her heart was more rapid in its action than normal: hence I gave her, in addition to the gallic acid and ergot mixture, the following:

℞ Liq. potass. cit., fℨj ;
Spts. æth. nit., fℨij ;
Tr. aconiti rad., gtt. xv ;
Syr. limonis, fℨiv ;
Aquæ, q. s. ad fℨij. M.
Sig.—Teaspoonful every two hours.

Wednesday morning I found her feeling somewhat better, though still having slight fever; pulse 124 and moderately weak in character. I did not detect any abnormal heart-sounds. I removed the lint packing without any further bleeding, and with much relief to the patient. I then ordered tincture of digitalis in three-drop doses every three hours, and also the following:

℞ Quin. sulph., gr. viij ;
Tr. ferri citro-chlorid., fℨj ;
Syr. tolu, fℨj ;
Aquæ, fℨvij. M.
Sig.—Teaspoonful every three hours.

Thursday I found the patient—to use her own language, well—evidently much better. Fever had entirely subsided ; the heart's action remained abnormally rapid. The cervical glands were slightly enlarged, but no enlargement of the tonsils and apparently no inflammation of the fauces. Treatment was continued, with the addition of more nourishing food, beef-tea, wine-whey, etc. The child seemed so much better that I said it might come to my office the next morning, instead of my going there.

Later in the same evening she took a sudden change for the worse ; but I was not sent for until Friday morning. Now the patient was suffering from high fever, 104° F. in the axilla ; pulse 134, compressible ; the cervical glands much enlarged and very hard ; the bowels had not been moved for twenty-four hours ; the tonsils were but very slightly swollen ; there were no patches in the throat. Thinking that possibly she was developing a malignant form of diphtheria, I at once put her on the calomel treatment until the bowels were moved, giving her three grains repeated in two hours, and then two grains, when the bowels were moved freely and the calomel was stopped. I also gave suppositories of two and a half grains of quinine every two hours ; also

℞ Liq. ammon. acet., fℨj ;
Spts. æth. nit., fℨij ;
Syrupi, fℨiv ;
Aquæ, fℨij. M.
Sig.—Teaspoonful every two hours.

I continued the tincture of digitalis in five-drop doses every three hours. I also applied hot flaxseed-poultices to the enlarged glands, and at noon plenty of beef-tea and milk ; but the child did not care for food, and it was difficult to get her to take any nourishment. At mid-day I noticed for the first time, although I had carefully and frequently listened before, a systolic heart-murmur. The temperature was but little affected during the night, and next morning (Saturday) at 7.30 A.M. I found it as high as ever: 104° F. in the axilla. Fearing that endocarditis had set in from the continuance of high fever and the heart-murmur, I at once applied a mustard-plaster to the pericardium, followed by a poultice, giving internally potassium iodide and ammonium carbonate, continuing the digitalis, until noon, when I met Dr. J. M. Keating in consultation.

Physical signs showed, in addition to what has been mentioned, an enlargement of the spleen ; yet there was no history of malaria. Dr. Keating did not think that endocarditis had set in, believing the murmur to be rather of a hæmic character ; yet, as a stimulant to the heart, suggested the application of a blister ; internally very small doses of Basham's mixture every three hours, with the free use of alcohol, beef-juice in small amount, etc., the temperature to be kept down to 102° or lower by means of the wet sheet. On examining a specimen of the urine which had just been passed, and the first that I had been able to obtain, I found it to be of sp. gr. 1016, of a light straw color, free from albumen and sugar. The child could not retain either medicine or beef-juice. The nose again commenced to bleed, to prevent which I again plugged the nostrils. Soon large clots of coagulated milk were vomited, the result of having been given by half-cupfuls at a time, which was entirely contrary to my direction. Her stomach soon became settled, and she took brandy and crushed ice in small quantities. We wrapped her up in a

*

wet sheet and then poured cold water over her until the temperature came down to 101° in the axilla, which required about thirty-five minutes. She was then wrapped in a blanket. In two hours the temperature was again 104°. We gave several of the wet packs during the afternoon and evening, and, notwithstanding we were at the same time giving two and a half grains of quinine every hour by suppository, the same rise in temperature was observed after each. During the night she took her medicine regularly; alcohol and water and beef-tea were also administered.

Sunday morning (the day of her death) I found her to all appearance bloodless; pulse rapid and small; respiration shallow and too frequent; temperature rising to 104° after the wet pack, as before. During Saturday night she had removed the packing from the nostrils, which allowed a slight oozing of blood, and this, having been swallowed, gave rise to vomiting of clotted blood; this continued after the bleeding from the nose had been again checked, at intervals of ten to fifteen minutes, which gave me the belief that there was a slight hemorrhage into the stomach, these clots differing somewhat in form and color from those which I ascribed to the epistaxis. The heart became more rapid, 138 per minute, and the patient gradually sank. She died at 6.30 P.M., in great agony, giving two or three shrieks, which were quite loud, considering her weakened condition.

Dr. KEATING remarked that Dr. William Osler had kindly examined for him a slide of blood and reported as follows:

"Report on slide of blood sent by Dr. J. M. Keating; examination about three hours after withdrawal.—*Red corpuscles* present no special alteration in size or shape. *Colorless corpuscles* greatly increased in number, fifty or sixty in each field of the No. 7 Hartnack. They present remarkable variations in size; many are small, not more than one-third the size of the larger forms. They resemble the smaller colorless cells which Virchow has noted to be present in cases of lymphatic leukæmia. Many of the cells have feeble amœboid movements. *Nucleated red corpuscles* not observed. *Schultze's granule-masses* (often abundant in leukæmia) scanty."

The relation of the increase in number of the colorless corpuscles above noted to the increase in size of the glands and cytogenetic tissues is indeed hard to solve. The increase in size and hyperplasia of the spleen in leukæmia and anæmia are histologically identical. We must remember that the view that colorless corpuscles are changed into red corpuscles is not fully established; hence, also, that it is not proved that the excess of colorless corpuscles is due to failure in the change to red ones. In such cases the prognosis, when the disease is detected at its incipiency, may be favorable, under rigid treatment of fresh air, suitable diet, iron, quinine, and arsenic, and salt bathing; but in marked cases, that have existed for some time with advanced symptoms, the result is fatal.

Dr. GOODELL inquired if there was any distinguishing point between purpura hæmorrhagica and lymphatic leukæmia. If there is a deficiency of red blood-corpuscles, why do red patches occur so easily?

Dr. KEATING remarked that the subject under discussion was dependent upon certain conditions which physiologists are still debating. In leukæmia we have as a diagnostic feature an involvement of the lymphatic system more or less, a hyperplasia of the tonsils, lymphatic glands of the peritoneum and of the intestines, also of the spleen and bone-marrow, all of them being more or less connected with red cell-formation; but the principal diagnostic point is the increase in number of the colorless cells, as is noted in Dr. Osler's report just presented. The hemorrhages in these cases are possibly due to a diapedesis or capillary rupture. In what is known as purpura hæmorrhagica there is an exudation of blood-cells or the hæmatin from their destruction into the rete mucosum and the papillary layer of the cutis; of course, capillary ruptures may occur with profuse hemorrhage. The blood-cells (red) are usually diseased; they become crenated or they cease to form rouleaux, and possibly the plasma may be at fault. The microscope alone will reveal the distinguishing features. Purpura may be considered a symptom accompanying a dyscrasia in which the blood itself is involved, not merely the organs of its production.

(To be continued.)

CLINICAL SOCIETY OF MARYLAND.

A STATED meeting of the Society was held October 16, 1885.

Dr. N. G. KEIRLE exhibited specimens and made the following remarks on

INTUSSUSCEPTION OF THE BOWELS.

Of the entire thirty feet of intestine, no portion claims more earnest attention from the practitioner than that small segment lodged in the right iliac fossa. Here the ileum enters the cæcum, from which depends the vermiform appendix; here is the most frequent seat of intussusception; here are found typhlitis and perityphlitis, idiopathic and traumatic, with resulting abscess and imminent peritonitis, demanding timely diagnosis and prompt surgical interference. While, as has just been said, the diagnosis must be timely and action prompt, yet in no class of cases does nature sometimes wait upon art with such long-suffering patience, and often waits in vain. The following is an instructive case. The clinical notes have been

furnished by Dr. E. V. Hood, Resident Physician to the City Hospital.

Peter Dracolliano, Italian laborer, aged 27, was admitted into the City Hospital August 13, 1885. It was ascertained that, four days before, he was attacked with vomiting and pain in the belly. No diarrhœa in the beginning, but a day or two afterwards the bowels were loose and some blood was discharged with the evacuations.

Condition on Admission.—The features indicate great pain and anxiety; the tongue is dry and slightly coated; the abdomen is much swollen and tympanitic; there is slight jaundice; patient complains of constant thirst; pulse, temperature, and respiration normal. He was given twenty grains of calomel by the mouth, and an enema of soapsuds and valerian. This relieved the tympanites and pain somewhat, but the calomel failed to operate.

On the 14th another injection was given, of soapsuds and asafetida, and fifteen drops of spirits of turpentine were given internally. Relief of the abdominal distention, but no fæcal discharge, followed. The patient vomited often, the matters vomited being very offensive and of a bilious character. Complete anorexia.

August 15. No flatus or fæcal matter passed by the patient since he has been in the hospital. Hypodermic of one-half grain of morphine, with another enema of soapsuds containing some oil of peppermint.

On the 16th, the tympanites and pain extreme; patient rolling about in great agony; no stool; fæcal vomiting; extreme thirst. Half a grain of morphine hypodermatically produced some relief. At no time could any lump be detected.

The patient died at 3 A.M. of the 17th, three and a half days after admission.

"All autopsies should record conditions with a view to surgical guidance," is an injunction of Mr. Hutchinson in reference to this disorder. The following description is an attempt to comply with this injunction.

The autopsy in the above case revealed intussusception of the ileum six inches above the ileo-cæcal valve. The intussusception is nine centimetres long, and, when evolved, eighteen centimetres. Both mucous and peritoneal surfaces were dark-colored and softened, as compared (by scraping) with sound tissue. The peritoneal coat is untarnished: this condition is probably one of intense congestion. At the seat of inception (neck of the sac) is a constriction formed by a layer of lymph, which, agglutinating the adjacent peritoneal surfaces and extending into the submucous tissues, projects the mucous surface of both the entering and receiving gut. This band does not entirely encircle the gut, but, starting from its mesentery, forms about a half-circle around the intestine. It is one centimetre wide, two centimetres long, and five millimetres thick. The calibre admits the tip of the index-finger.

Placing the colon like a hose upon a water-faucet, a full stream is turned into it, and passes through the valve in this reversed direction without obstruction, but being stopped at the tip of the intussusception, which it thus fails to reduce. Reduction is, however, effected with moderate pressure upon the fluid by grasping the gut. In the process of reduction both surfaces of the gut are lacerated at the point of constriction formed by the effused lymph above referred to. When reduced, therefore, the gut shows two rents, eighteen centimetres apart, indicating the point of adhesion at the neck of the sac.

In a second case (of which the specimen was shown) nothing was known of the clinical history except that it was acute in its course. The subject was an adult male. About eleven centimetres of the ileum were intussuscepted in the cæcum. The invaginated gut lies curved like a horseshoe in the cæcum, so that it can be reposited only by immediate manipulation; neither air nor water could have effected it.

Mechanism of the Accident.—"Peyer, in 1677, asserted that intussusception was due to loss of contractile power. It is also said to be due to blows, diarrhœa, cholera, local paralysis or spasm, analogous, when in the ileo-cæcal region, to prolapse of the rectum from tenesmus.

"Leubuscher, at the suggestion of Nothnagel, made experiments upon rabbits. In twelve the intestine was compressed, but in only one was there any effect produced. In this the compressed part became entirely enclosed in the part above. In one experiment with electrical stimulation there was no effect at the point where the stimulus was applied, but at a distant part intussusception took place, the bowel being outside of the abdomen. No local cause for the invagination could be discovered: it seemed to be purely the result of vigorous peristaltic action. On the other hand, the experiments afford little support to the view that the lesion results from localized intestinal paralysis.

"In seven cases the nerve in the mesentery was cut. In two of these there was invagination to the extent of one-half centimetre; in a third invagination took place at a distance. The lower uninjured part passed into the upper paralyzed part. In man the descending form of invagination is almost invariable."

Some conjectures as to the mechanism of this accident in this situation are offered in order to evoke discussion. In the normal peristalsis, when expulsive (not propulsive), a series of transient quasi-intussusceptions, with immediate release, or some movement of this character, may occur, at least as regards the mucous layer of the intestine. If the serous and muscular coats of the ileum at

its junction with the cæcum be divided by a circular incision, the ileo-cæcal valve may be pulled out into the ileum and thus obliterated. This "valve" is merely an inflection of the mucous membrane of the ileum. If the cæcum be greatly distended with flatus, strong traction will be exerted on the mucous membrane centrifugally. Hence a concomitant bowel-disorder of this nature may be assumed to favor the production of the accident under consideration. Indeed, it would seem that both in cases of intussusception and in those in which foreign bodies lodge, there is pre-existent predisposing bowel-disorder. Intestinal invagination in the moribund is due to errors of peristalsis.

Prognosis.—Dr. J. Lewis Smith, in a most instructive article (*Amer. Journ. of Med. Sciences*, January, 1862) on intussusception in children, quotes Rilliet as asserting that ileac intussusception is very common in children, readily overcome, and seldom fatal; but when the ileum is invaginated into the colon, or the entire invagination occurs in the colon, the condition is much more grave. Of forty-eight cases, forty-five occurred in the ascending colon,—*i.e.*, ileum into cæcum, and cæcum into colon. In some cases the invagination may be so extreme that the cæcum and valve may present at the anus. Of these forty-eight cases, in seven portions of the bowel were discharged per anum and the patients recovered. The ages of the patients ranged from five to twelve years. The process of sloughing occupied, on an average, ten days. There is thus about fourteen per cent. of natural recovery from intussusception in children under twelve.

Dr. Smith remarks that in intussusception sloughing is conservative, but in hernia destructive,—*i.e.*, fatal. Abdominal section may avert the latter termination, but cannot aid the former. He expresses his views as follows: "If the tumor can readily be detected by external examination; if its position be favorable; if the patient is a robust adult, the propriety of the operation in some instances might be seriously considered; but there must be very few surgeons who would recommend it in the child under any circumstances."

Mr. Hutchinson in 1858 advised non-interference by operation; but in 1875, after a successful case of gastrotomy, he reversed his opinion. When left to nature, the mortality in intussusception is about seventy-five per cent.; according to Mr. Treves, seventy per cent. In chronic invagination, if left to nature, the mortality is eighty-six per cent.; while in chronic strangulation the mortality after operation is ninety-two per cent. (only two successful cases in twenty-seven).

It is probable that the danger from gastrotomy itself is not very great. Hence, if the diagnosis of intestinal invagination can be positively made very soon after the occurrence of the accident, the promise of a cure is increased above the twenty-five to thirty per cent. of natural recoveries. Those who would recover anyhow would thus be needlessly operated upon for the benefit of the additional successes. In the cases where sufficient time has elapsed to permit the gut to become gangrenous or adhesions to take place, nature should not be interfered with in her endeavors to restore the perviousness of the bowel. Surgical interference in this stage diminishes the patient's chances for recovery.

According to Mr. Benjamin Phillips (Erichsen's "Surgery"), gastrotomy and division of stricture are "justifiable when three or four days have passed without any relief from ordinary means, constipation being complete and vomiting of fæcal matters continuing." This limitation as to time had expired in the case related before the patient's admission.

The recoveries after operation for simple artificial anus by peritoneal section are forty-one per cent.; when done behind the peritoneum, sixty-one per cent. Hence, when possible, as perhaps in ileo-cæcal intussusception,—*e.g.*, the case from which the second specimen shown was obtained,—the operation should be through the right lumbar region, thus avoiding incision of the peritoneum, except in some anomalous cases where the entire circumference of the gut is invested by that membrane.

An intussusception which has persisted acutely for four days may be regarded as chronic.

In acute cases, when spontaneous recovery occurs, the invaginated gut is separated and extruded between the sixth and twelfth days. There are, however, cases, very subacute in character, in which a month may elapse before this occurs. A very interesting case of this nature is recorded by Dr. Woodman (*Med. Times and Gazette*, vol. ii., 1870, p. 641):

Miss H., aged 41 years, on November 19 complained of pain and tenesmus in the hypochondrium. There were bilious vomiting, tenesmus, and scanty fluid, sometimes bilious, evacuations per anum. No lump could be detected. There was no stoppage of the bowels, no stercoraceous vomiting, no violent inflammation; yet, on December 19, one month from the beginning of the attack, she passed easily from her bowels at stool nine inches of the ileum. Two years thereafter the patient is reported as continuing in good health.

A case of this kind would probably be well adapted for operation at any time; but nature, though slow, is probably the best operator.

The operation of Mr. Treves seems to be based upon the statistics of strangulated hernia, between which and intussusception there is a strong analogy,—a family likeness with features of difference. "Of 69 cases of

strangulated hernia operated upon within 48 hours, 12 died, or 1 in 5.7 (over 17 per cent.), whilst of 38 cases operated upon after 48 hours had elapsed, 15 died, or 1 in 2.5 (over 39 per cent.)."—(Erichsen's "Surgery.")

In the United States, the annual mortality from intussusception is 800, the death-rate being 70 per cent. If the analogy between the operation (laparotomy) for this condition with that for strangulated hernia is borne out in practice,—and the chances are in favor of this,—operation within forty-eight hours should reduce the mortality-rate to 17 per cent.: so that we may say that 424 lives yearly ask the profession of the United States, "What shall we do to be saved?"

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held November 5, 1885, the President, A. JACOBI, M.D., in the chair.

A SKETCH OF THE LIFE OF J. L. LITTLE, M.D., AND OF THE TWENTY-FIVE YEARS IN WHICH HE PRACTISED SURGERY IN NEW YORK.

Dr. D. B. ST. JOHN ROOSA read the paper, in which it appeared that Dr. Little was of Scotch-Irish and English ancestry; was born in Brooklyn, 1836. He received such education as the schools of his city afforded, and then became a clerk in a book-store. Here he had opportunity to read works on medicine, and later became a student under Dr. Willard Parker. He successfully passed a competitive examination, and became junior assistant in Bellevue Hospital. He graduated at the College of Physicians and Surgeons in 1860, and resigned his position at Bellevue to enter the New York Hospital, then the centre of surgery in this country. In this hospital Wright Post and Kearney Rodgers had won their fame, and here Valentine Mott, who was still living and lecturing upon surgery, had tied the arteria innominata. He was consulting-surgeon with Alexander H. Stevens, John C. Cheesman, and Alfred C. Post; the active members of the surgical staff were Gurdon Buck, John Watson, Thaddeus M. Halsted, Willard Parker, William H. Van Buren, and Thomas M. Markoe. Of all this number, only Drs. Post and Markoe survived. In those days the thermometer was not employed; pyæmia, erysipelas, and hospital gangrene were dreaded foes; and antiseptic surgery, if practised in attempts at absolute cleanliness, was not understood as now, when patients after operations are saved not as by fire, but as a matter of course. It was in the New York Hospital that Dr. Little devised his method of making and applying plaster-of-Paris splints. He reported many cases occurring in the wards in the *American Medical Times*. During the War of the Rebellion Dr. Little's services were on several occasions furnished to the government. He was clinical assistant to Dr. Parker, who was then Professor of Surgery in the College of Physicians and Surgeons. In 1863 he was appointed Lecturer in the college; his chair was enlarged in 1868 to that of Operative Surgery and Surgical Dressings. Dr. Little was popular as a lecturer; his manner was earnest and simple. After sixteen years of teaching in the College of Physicians and Surgeons, he resigned his place and became Professor of Clinical Surgery in the University of the City of New York. He became Professor of Surgery in the University of Vermont in 1875. Here he worked with great zeal and success. His "luck" became proverbial, for his operations were pre-eminently successful. Three years after his connection with the University of the City of New York, he resigned, with others, to establish the New York Post-Graduate Medical School. He was for many years surgeon to St. Luke's Hospital; in 1876 he became attending-surgeon to St. Vincent's Hospital. In August, 1884, it was discovered that he was suffering from diabetes; but he was able to continue his professional work until a few days before his decease, April 4, 1885. His fatal illness began with severe pain in the right iliac fossa, which led to general peritonitis. He passed away with the words, "I die in the Christian faith," on his lips.

Dr. PAUL F. MUNDÉ then read a paper on

ELECTRICITY AS A THERAPEUTIC AGENT IN GYNÆCOLOGY.

The author's object in bringing this paper before the profession was to make more popular a therapeutic agent which had a wide range of usefulness in gynæcology, but which was little employed. Any physician who was capable of making a correct diagnosis of his case could use the agent, but it would take more time than many specialists could devote to it. Probably not more than two cases could be disposed of in an hour. To be efficient, its use must be persisted in, and the benefit might not be apparent before some weeks. Fewer than two sittings a week would probably be of little use; they should usually be of half an hour's duration. The galvanic current had a far wider range of usefulness than the faradic. If the faradic current were employed, it would usually be beneficial in proportion to the strength of the current, but it ought not to produce great discomfort. The galvanic current should never give pain, and it was better to begin with a less powerful current and gradually increase it, but ceasing should discomfort follow. If employed intravaginally, the pole should be introduced before connecting the circuit, and the current should be diminished before withdrawing, thus avoiding pain. Usually it made little difference, in his experience, whether the one or the other pole was applied at the seat of the disease.

The following conclusions were given:

1. Electricity, locally applied, is a valuable agent in gynæcology, and should be more widely used than it is.

2. The remedy, if properly used and on correct occasions, cannot do harm.

3. It should be used only in chronic conditions; the galvanic current should not give pain.

4. The faradic current is indicated in deficient development or want of tone of the genital organs. The object of the faradic current is to stimulate the organs to increased growth and activity.

5. The galvanic current is used to promote absorption of exudative deposits, to allay pain, to excite retarded action, and occasionally to act as a caustic.

6. Perseverance is necessary to success.

7. Acute and subacute affections generally contra-indicate the use of electricity.

8. This method is often successful where other methods of treatment cannot be borne by the patient.

9. In some incurable conditions temporary improvement and relief from pain can be obtained from electricity without discomfort or danger to the patient.

The following were some of the conditions in which Dr. Mundé had employed electricity: In uterine displacements: when due to elongation of the ligaments, little effect was produced; more could be expected of the faradic current in flexions than in versions. In fibroid tumors: here his experience had been limited, but Dr. Freeman, of Brooklyn, had had successful results in three cases; in chronic pelvic cellulitis, lymphangitis, and neuralgias depending upon these conditions, the galvanic current proved of benefit in relieving pain and softening adhesions; he would not employ it in acute and subacute cases. In pachysalpingitis this method could be employed for the relief of pain and to tide the case along where it was not desirable to perform Tait's operation; in hyperplasia uteri the galvanic current would relieve reflex neuroses and diminish the size and hardness of the uterus; in subinvolution he had used the faradic current with benefit; in amenorrhœa of different forms benefit had followed the use of electricity; in deficient development of the uterus and ovaries electricity could be employed in some instances with advantage.

The paper was discussed by Dr. Freeman, Dr. Rockwell, Dr. Birdsall, Dr. Boldt, Dr. Malcolm McLean, the President, and by the author. Dr. Freeman narrated three cases, referred to by the author, in which he reduced fibroid tumors by the introduction of a needle connected with one pole of a battery into the tumor through the vagina or anterior abdominal wall; no serious reaction had followed. He now employed static electricity forty times where he employed other forms once: it had the great advantage of dispensing with disrobing the patient. The benefit derived from electricity in the relief of pain was most important. Dr. Rockwell and Dr. Birdsall were of the impression that the galvanic current would be indicated in subinvolution.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held November 11, 1885, the President, JOHN A. WYETH, M.D., in the chair.

STRANGULATED HERNIA OF LARGE SIZE.

The President presented part of the genito-urinary apparatus and about ten feet of large and small intestine, found in a double hernia, the entire tumor having measured about forty inches in circumference.

The patient was 53 years old, and was admitted to Mount Sinai Hospital October 28, 1885. He had had a rupture on the left side of seven years' duration, and had worn a truss for some time. For the past three years the scrotum had become distended, and for six months past he had experienced difficulty in micturition. He had been ruptured on the *right* side for three or four weeks. On the left side the hernia had not been reduced for three years, and had been growing larger. He had not had a free movement from the bowels for five days previous to admission. He had not vomited. There had been retention of urine for twenty-four hours. As it was evident that the patient could not recover after an operation, none was performed. Pain was relieved by opiates. He died two days after admission. The specimen was chiefly of interest because of its immense size, being the largest Dr. Wyeth had ever seen. The older hernia was smaller than the other. Dr. Wyeth had seen a similar case within twelve months, in which the hernial tumor, however, was not quite so large. As in this case, there had been no stercoraceous vomiting, and there had been slight movement from the lower portion of the gut. The second patient was 85 years of age.

MYOCARDITIS AND CHRONIC DIFFUSE NEPHRITIS, WITH OBSCURE SYMPTOMS.

Dr. John C. Peters presented microscopical slides showing chronic myocarditis, and related the history of the case of a bachelor, 67 years of age, whom he had known for the past thirty years, and who had never been really sick until the last spring, although he had had the appearance of being weakly. He was very exact in all his habits, and was perhaps too abstemious in the matter of diet. He had suffered from fever and ague in his early years, and he thought he had suffered slightly with malaria since. Last May he looked ill, suffered distress in the stomach, and shortly had considerable dyspnœa and orthopnœa. The temperature at no time rose

above 102.5°. Capillary bronchitis developed, and also pulmonary œdema to a slight extent, most marked on the left side. The symptom which gave most apprehension was the extreme weakness of the heart. The patient gradually regained his strength, but Dr. Peters and the consulting physicians diagnosticated dilatation of the right side of the heart, which disappeared later. The urine had been repeatedly examined for many years, and nothing abnormal was noticed until on this occasion, when it contained some albumen. The albumen disappeared when convalescence set in. The patient went to Saratoga, where he had a relapse, but was afterwards again able to walk some distance. Another relapse occurred, which resulted, after ten days, in death. The urine contained albumen only during the times of the relapses, and some casts (the nature of which he could not recall) were found by a microscopist. The last attack commenced with difficulty in breathing. The autopsy showed the pericardium closely adherent to the heart by old adhesions; no fluid in the sac. This attack of pericarditis could not have occurred during the past twenty years. There seemed to be some difference of opinion among those who made or saw the result of the post-mortem examination. Dr. Peters thought there was some cardiac dilatation, most marked in the left ventricle. During life they had supposed it to be in the right ventricle. The microscopical examination showed chronic interstitial myocarditis. There was some turbid serous fluid in the pleural cavities; adhesions of the apex of the left lobe; and recent bronchitis. There was diffuse interstitial nephritis, accompanied by slight tubular changes.

Dr. Waldstein remarked that we often find at post-mortem examinations the condition of the kidneys described by Dr. Peters, without there having been any history pointing to disease of those organs.

Dr. Carpenter had made the microscopical examinations, and said that, while there was chronic diffuse nephritis, the appearance of the epithelium of the kidneys would not lead one to suppose that there had been marked signs of the kidney-lesion in the urine.

DOUBLE HYDROCELE IN AN INFANT TWO MONTHS OLD.

Dr. R. Van Santvoord presented a specimen illustrating double hydrocele in an infant which had died in the asylum, aged 2 months. The hydrocele had been noticed since it was a month old. It did not communicate with the abdominal cavity.

LUPUS OF THE LARYNX.

Dr. Van Santvoord also presented the larynx of a boy, who died at 14 years of age, having had lupus commencing in the nose, destroying that organ entirely, also the upper lip, the mucous border of the lower lip, the alveolar processes between the canine teeth, the hard and soft palate. The nasal septum had fallen out; the body of the sphenoid had become bare; the pharynx was apparently not involved. In the larynx he found general thickening of the mucosa. The mucous membrane lining the ventricles and immediate neighborhood was dotted over with small, nipple-like processes. The boy had lived up to five days of death in comparative comfort; then there developed intense headache, which passed to delirium, coma, and death. The base of the brain was found coated with a thick layer of lymph, distributed about as is usually seen in tubercular meningitis, but no tubercles were found. The meningitis had arisen from extension of the diseased process from the sphenoid, the body of which had become necrotic. There were amyloid changes in the liver and stomach, but no tubercles were anywhere found. The case was also interesting in its bearing upon the alleged identity between lupus and tuberculosis. Dr. Van Santvoord thought it hardly possible that the process could have been a tubercular one, the lesions having been so extensive, and there being nowhere any tubercles.

Dr. M. Putnam Jacobi said, regarding the identity between tuberculosis and lupus, that Hueter had stated that if only one in twenty children having a localized tuberculosis was going to have general tuberculosis, it would hardly justify excision of the diseased bone. In the light of this statement it was not surprising that there was not general tuberculosis in Dr. Van Santvoord's case, although the local disease may have been of a tubercular nature.

Dr. Prudden said that if the presence of the tubercle-bacillus indicated tubercular inflammation the identity between lupus and tuberculosis had been established.

SCIRRHUS OF THE STOMACH AND TUBERCULOSIS OF THE RETRO-PERITONEAL GLANDS.

Dr. Louis Waldstein presented specimens from the body of a man who had suffered with chronic pneumonia in the left apex, the physical signs disappearing later. He was well then until two years ago, when he was taken suddenly with symptoms then regarded as intermittent fever. During the past two years this fever continued from day to day, antipyretics having no lasting effects upon the symptoms. The physician who examined the patient two years ago found a tumor in the epigastrium, a little to the right of the median line, which he regarded as cancer of the stomach, although there seemed to be no special grounds on which to base such a diagnosis. Many physicians saw the patient in consultation, who detected an intumescence in the abdomen, which seemed to be continuous with the tumor in the epigastrium. The post-mortem examination showed tuber-

culosis in the left lung. The stomach did contain a diffuse scirrhous cancer, with no tendency to ulceration: hence the absence of special symptoms of cancer. The retro-peritoneal glands were greatly enlarged, and contained much cheesy matter. There were no signs of metastasis of the carcinomatous disease in the stomach.

Dr. Peters remarked that it used to be considered that tubercle and cancer never occurred in the same patient, the one disease precluding the other.

NECROTIC CYSTITIS.

Dr. T. M. Prudden presented the bladder of a woman who died a few days after childbirth. A month previously she had paralysis of the right side of the body, and complained of pain in the back. At one time she had difficulty in urination, but lately had made water without difficulty. The urine contained albumen. Microscopical examination was not made. There were no other symptoms referable to the bladder. The post-mortem examination showed a tumor occupying the left half of the pons. There was basilar meningitis and pachymeningitis purulenta of part of the petrous and sphenoid bones. The lesion to which special attention was called was situated in the bladder, and illustrated the condition of necrotic bladder preceding the exfoliative stage.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, OCTOBER 22, 1885.

The President, J. C. WILSON, M.D., in the chair.

DR. J. COLLINS WARREN read a paper on

A COMPARISON OF THE CHANGES IN ARTERIES AFTER LIGATURE AND IN THE DUCTUS ARTERIOSUS AND UMBILICAL ARTERIES AFTER BIRTH.*

DISCUSSION.

Dr. S. W. GROSS said, in view of the fact that Dr. Warren's teaching seemed so directly opposed to that of other observers, he would like to have some points cleared up. He would therefore ask if Dr. Warren held, first, that, instead of the external coat where it is included in the ligature sloughing and coming away with the ligature, the pressure of the ligature sets up an irritation which causes the adventitia to return to its embryonic state with a reconversion after the ligature has cut through this to connective tissue; and, second, whether the repair of arteries was brought about by the ingrowth of the cicatricial tissue, which he likened to provisional callus, together with some proliferation of the muscular cells of the media.

Dr. RANDALL said that, as the result of careful study of the subject, he had always found the clot present at first, and that it was honeycombed, even in the first few days, by the contraction of its fibrin: through the spaces thus formed the blood seemed to be circulating. Cells, either original white cells or of endothelial origin, occupied the walls of these cavernous spaces, and seemed to sheathe them. The red cells early melted down into a homogeneous mass, furnishing the framework upon which the reparative tissue was built. The "plastic clot" of some observers he had not seen,—the new cells being distributed throughout the old clot as well as upon the vessel-walls, and not specially collected in the immediate neighborhood of the ligature. The obliteration of the vessel was accomplished by the growth and contraction of the trabeculæ of new tissue built upon the remains of the original blood-clot. Even close to the ligature he had not found the vessel-walls greatly altered, merely showing a great increase in the nuclei and in the number and size of the vasa vasorum, the lamina elastica being distinct and, as a rule, intact. Towards the end of the first month the new tissue was largely spindle-cells, but careful staining had given no suggestion of muscular tissue. But, not having carried his study beyond the first month, he had no data upon this subject, since the development of muscular tissue is claimed to occur only at a later stage.

Dr. FORMAD was inclined to favor the views of Dr. Randall. The observation of Dr. Warren, that the new-formed connective tissue played the most important part, was to him entirely novel. He thought probably that pressure upon the artery from without, with consequent diminution in its lumen, might bring about a condition more analogous to the growth of fœtal life than to inflammation.

Dr. MEARS remarked: We are liable to be confused, in considering this subject, by the presence of the blood in the vessel. So far as the process of healing after ligature is concerned, we may consider only the structures which enter into the formation of the vessel-wall, which is complex in character and composed of connective, elastic, and endothelial tissues. Dr. Warren has given us a very clear demonstration of cicatrization as it occurs in these structures after application of the ligature.

Dr. TYSON said the most novel feature to him in Dr. Warren's observations was the part played by the muscular tissue. This apparent increase in the muscular tissue, he was inclined to believe, was really only a proliferation of intermuscular connective tissue. He was becoming more and more convinced that there was only one kind of inflammation, the interstitial. He feared that he might himself mistake a proliferating connective tissue with spindle-cells for muscular tissue. It is true that new-formed capillaries

* See summary contained in editorial on page 132.

and arterioles have muscular walls, but the development of these seemed to him to be a slower process. He had expected to find a process of repair in the ductus arteriosus different from that in an ordinary artery. This process he had expected would be a true end-arteritis, for it seems that the conditions of closure here are rather different from those in the ligaturing of an ordinary artery and in the umbilical artery, where we have also ligation practised.

Dr. WARREN, in closing, said, in cases where there is much breaking down and little repair there might be a sloughing of the external coat, yet in his experiments this part of the arterial wall did not slough, but was simply absorbed by the granulation-tissue, as is the ligature itself in some cases. In the normal condition even the elastic lamina is not a perfectly continuous plate. He did not refer to these breaks, however, but to numbers of little ruptures incident to the pulling out of the wound of an artery in the act of ligature. However, this need not necessarily occur. He had not attempted to identify anything like muscular tissue early. This could not be recognized till we had a permanent cicatrix formed. He had carefully eliminated all sources of error, and it seemed to him that in almost all cases there was a considerable number of these muscular cells. The layer was not always as well marked as in his diagrams. Especially was this true of human cases, but these had all been in alcohol for some years. Of the fresh specimens he had selected only those in which he had considered the process complete. In a specimen which he had here to-night, through an opening in the lamina elastica cells could be traced from the muscular layer, those in the inside resembling exactly those outside. These facts, together with the fact that we have normally a few muscular cells inside of the lamina elastica, led him to believe in the proliferation of the muscular tissue. The disintegration of the blood-clot is accompanied by granulations growing inward from the callus, there being two sets of blood-vessels,—one in the granulations, the other (blood-spaces, rather) in the clot itself. These unite about the end of the first or second month.

W. E. HUGHES, M.D.,
Recorder.

MEDICAL JURISPRUDENCE SOCIETY OF PHILADELPHIA.

AT the meeting of the Medical Jurisprudence Society of Philadelphia, held on Tuesday evening, November 10, Dr. John J. Reese in the chair, Thomas W. Barlow, Esq., read a paper prepared by himself and Dr. John H. Packard, entitled

ON THE EXTENSION OF PRIVILEGE TO COMMUNICATIONS BETWEEN PHYSICIAN AND PATIENT.

The object of the paper was to urge the passage of a law making the relations between physician and patient privileged, and not subject to judicial inquiry. In six of the States such a law has been upon the statute-books for many years. The New York statute, which the speaker favored, is as follows: "No person duly authorized to practise physic and surgery shall be allowed to disclose any information which he may have acquired in attending any patient in a professional character, and which information was necessary to enable him to prescribe for such patient as a physician, or to do any act for him as a surgeon."

The speaker said that the Supreme Court of the United States in a certain decision has declared, at least by indirection, that the relations of a physician and his patient are among the privileged class. A physician's office ought not to be converted into a detective bureau. The disclosure of a professional secret even under legal pressure is felt to be unprofessional and dishonorable. Under the law as at present in Pennsylvania a physician is obliged to answer questions of the most private character and concerning family secrets. The absence of such a law as is desired gives facilities to blackmail by unscrupulous physicians. The objection that such a law would prove an obstruction to the discovery of crime, it was claimed, was not well founded. The speaker had examined all the cases reported in New York since their law went into operation, fifty-seven years ago, and there was only one case where crime went unpunished, and even in that case the prisoner was afterwards convicted without the physician's testimony. The proposed law would relate only to such communications as were made in confidence to enable the physician to prescribe for the patient. Its purpose is to enable a patient to talk plainly, and the physician to invite the confidence of the patient and prevent a breach of that confidence. Knowledge gained by the physician under such circumstances should be privileged, but knowledge gained under circumstances other than for the purpose of prescribing for the patient is not, under the decisions, privileged. The courts have carefully distinguished between information disclosed to a physician necessary to enable him to prescribe and information not necessary for such a purpose. The law will inquire into the circumstances in each case, and will decide whether the physician can be made to speak. If he should obtain information respecting the criminal acts of people other than his patient, then it is his duty to disclose as to those other persons.

After a general discussion, Dr. Packard said that the experience of New York was confirmatory of the value of the law. The point of it is to secure free and unrestrained communication between physician and patient for the benefit of the latter. Doubtless in rare cases some injury might be done to the cause

of justice, but the general benefit to the whole community would more than offset a case occurring now and then. He held that a physician has duties as a citizen as well, and if he should while treating a patient come into possession of information concerning the criminal acts of others, it is his duty to disclose that a crime has been committed.

On motion, the chair appointed Dr. Packard and Mr. Barlow as a committee to report at the next meeting the best means of securing the passage of such a law. It was stated that the law which it is proposed to ask the Pennsylvania Legislature to pass is precisely like the New York law above quoted.

T. M. Daily, Esq., and S. Spencer Chapman, Esq., were elected members of the Society, and Dr. G. Milton Bradfield to the office of Recorder, in place of Dr. S. S. Cohen, resigned.

MISCELLANY.

Municipal Food-Inspection in Paris.—The same sunlight serves the just and the unjust, and the achievements of science are often as successfully applied to the purposes of fraud as to those of human progress. The scientific knowledge that gives ability to pass judgment on a substance supposed to be unwholesome or adulterated must be at least as great as that required for the selection of the adulterant, and the expense of sanitary investigations, therefore, affords a certain immunity to the unscrupulous dealer or manufacturer. Some system is therefore desirable by which an aroused suspicion may be confirmed or a guarantee of purity or wholesomeness obtained at a comparatively small cost.

In Paris this demand has been supplied since 1881 by the opening to the service of the public of the municipal laboratory established in 1878. A report of the operations of the laboratory for the first three years of its existence has recently been published, and contains detailed statements of the objects in view, the methods followed, and the expenses of the system. The *personnel* of the laboratory consists of twenty-seven chemists, including the director, M. Charles Girard, and his *sous-chef*, twenty expert inspectors, two servants, two laborers, and four clerks. The total salaries for the year 1883 amounted to one hundred and forty-seven thousand two hundred francs; this sum was swelled to two hundred and six thousand eight hundred and ninety francs by the running expenses, including porterage of samples, purchases of chemicals, glassware, and apparatus, and insurance. The future budget is estimated at two hundred thousand francs a year.

Samples sent to the laboratory for analysis are received by one of the clerks, who enters in a stub-book the character of the substance, the name and address of the sender and those of the merchant from whom it was purchased, the date, and the number of the analysis. These items are duplicated on the receipt which is detached and given to the depositor, who is told when to return for a report. The sample is correspondingly numbered and sent to one of the chemists, who examines it in its order.

Qualitative analyses—those in which only the general character of the substance is desired—are made gratuitously, and the report denominates the sample as good, passable, bad but not injurious, or bad and injurious; in most cases such a verdict can be reached only after a complete or quantitative analysis, but the detailed results are not communicated in the report. If a report giving the exact composition of the sample as shown by quantitative analysis is desired, a fee of from five to twenty francs is charged.

Samples for gratuitous analysis and those which are collected by the inspectors may also be deposited at the nearest police-station, from which regular collections are made by the laboratory wagon.

The inspectors are obliged to examine the markets and all shops in which alimentary substances are sold. They are provided with microscopes and a small case of chemical reagents. Any substance which they find to be unquestionably bad or spoiled may be destroyed on the spot; in case of suspicion two samples are taken, both of which are sealed and numbered, and certified by the signature of the dealer; one of these is sent to the laboratory, while the other is preserved for a counter expert analysis if the decision of the laboratory should be disputed. Each inspector must report at the laboratory every evening; his report is entered in the journal, and his duty is assigned for the morrow.

For the more common products the chemists employed are specialists; some are exclusively occupied in the analysis of wines, others in the examination of milk, etc., this being the only method by which indisputable results can be obtained with the necessary rapidity; but those who analyze one kind of samples are competent to examine others when occasion requires. No other information than the number of the sample and its kind is furnished the analyst, whose results are written out on special forms attached to the label of the sample, and passed to one of the clerks. They are then arranged in a stub-book, and the report is filled out, signed, and detached, and forwarded to the police-station from which the sample was received, or is retained until called for if the sample was left at the laboratory.

If a sample collected by an inspector turns out to be bad, a report with the result of the analysis is sent to the secretary-general, and the matter comes to the cognizance of the courts. The laboratory does not prosecute;

it determines only purity, alteration, or falsification; the responsibility for seizure and prosecution then rests on the courts.

In 1883, 14,686 samples were examined; of these 6749 were analyzed gratuitously for the public, 550 were paid, and the remainder were brought in by the inspectors. 7144 of the samples were wines, and 4172 were milk; then, in the order of number, come butter (364), water (255), pepper and spices (254), flour (205). Besides these analyses, which required 87,762 separate determinations of substances, 45,633 inspections were made of markets, restaurants, etc., and 1388 lots of injurious aliments were destroyed by the inspectors.

As an example of the results of the inspections and analysis, 1037 samples of milk were examined in 1881, and of these fifty per cent. were found to be fraudulent by the addition of water and removal of cream; in 1882, 2134 samples were analyzed, and the fraudulent had decreased to thirty per cent. The average daily consumption of milk in Paris is 250,000 litres; assuming that of this quantity 100,000 litres are diluted with a moderate quantity of water, say five per cent., 5000 litres of water are daily sold for milk; the resulting profit to the dealer and loss to the public would amount to one thousand francs a day, or three hundred and sixty-five thousand francs a year,—much more than the total expenses of the municipal laboratory.

In addition to the analysis of aliments, the work of the laboratory includes the examination of pharmaceutical products used in perfumery, the estimation of lead in tinned surfaces and in the solder of cans used for preserving food, the analysis of coloring-matters used for toys, bonbons, and syrups, the disinfection of lodgings and carriages which have been exposed to infectious diseases, the search for gas-leaks in cellars and sewers, and, indeed, all chemical investigations that may be of interest to the public health.

It is interesting to note that nearly all the hair-dyes, powders, cosmetics, and depilatories examined contain large quantities of mineral poisons, among which are nitrate of silver, sulphate of copper, sugar of lead, corrosive sublimate, and arsenic. Of thirty-one hair-dyes and toilet-waters analyzed, twenty-four were found to contain considerable proportions of one or more of these poisons. Two out of five face-powders are reported bad. Yet these are examples of celebrated French "toilet-necessities."

Of ninety-six specimens of toys examined sixty-four were decorated with poisonous colors, the remainder being inoffensive.

The continual increase in the number of samples examined prevents a fair estimate of the effect of the laboratory on the proportion of frauds; but a diminution is nevertheless noticeable. Since, however, the general results are not of a character to increase public faith in the commercial integrity of dealers, the publication of the percentage of bad samples has been suspended since 1882, and will probably not be resumed until there is a marked improvement.

NOTES OF AUTOPSY OF JOHN MCCULLOUGH, TRAGEDIAN.—Examination ten days after death made by Drs. Hugo Engel, Chas. K. Mills, J. H. Lloyd, J. M. Barton, W. R. D. Blackwood, and others present by invitation. Body in excellent state of preservation. The head only was examined, by special request of the relatives. No scar, depression, or marked irregularity of contour was noted as existing on either side of the calvaria. The dura mater was firmly adherent, especially along the lateral borders of the superior longitudinal sinus. In this situation, on both sides of the sinus, especially at the vertex, were observed small, white, granular masses (Pacchionian ?). No other abnormality was observed in the dura, no discoloration, thickening, or evident inflammatory change. Some of the superficial vessels, however, had rigid almost cartilaginous walls: this was especially observed in the left temporal region. No excess of cerebro-spinal fluid was found.

The large venous branches in the pia were enlarged, injected, and cord-like. The pia showed milky opacities along the course of the vessels, and over the fissures of Sylvius and Rolando. The same conditions were noticed in the pia covering the cerebellum.

Brain-structure of the convolutions firm and well preserved, but soft in the interior; the corpus callosum and ganglia were torn in removing the brain. Where the pia was most opaque the underlying cortical structure adhered to it, and came away with it when removed. This was not noted elsewhere. Deep in the fissure of Sylvius adhesions were found between the adjoining lobes. The basilar artery, both middle cerebral arteries and their branches, showed extensive degenerative changes in their walls, principally in the form of white spots which projected into the lumen of the vessels, and which were decidedly resisting to pressure. Nothing noted in large sections of the brain through the ganglia. The diagnosis made during life of paretic dementia was thought to be confirmed by the autopsy.

ARTIFICIAL LIMBS made by A. A. Marks, New York, by a peculiar method of construction, are especially noted for lightness, durability, and naturalness. Many of the limbs made by this firm have been purchased by the government for its disabled soldiers; and it is stated that one was recently fitted for the son of the President of Peru, one for a prominent surgeon of Naples, and one for an *attaché* of the Japanese legation. These limbs are made to suit all ages, and can be ordered by mail, a perfect fit being secured by measurements entered upon blanks which will be sent upon application.

M. CHARLES ROBIN, Professor of Histology at the Paris Faculty of Medicine, has just succumbed to a fit of apoplexy at the age of sixty-four years. The death of M. Robin is a great loss to science. His American students, such as Professor Flint, Jr., and many others, who have since become learned in physiology, and often had to differ with him on certain points, will deeply regret the death of the master whose works and discoveries we all have more or less benefited from. Dr. Robin instituted and filled the chair of Histology at the Paris Faculty since 1852, and was elected a member of the Academies of Medicine and Sciences in 1858 and 1866 respectively. His publications were very numerous. Of the many important works we mention "Les Fermentations," published in 1847; "Programme du Cours d'Histologie," "Traité du Microscope," and "Anatomie et Physiologie cellulaire;" then afterwards, with M. Littré, the "Dictionnaire de Médecine," etc. M. Robin, since 1875, was the Senator for the Department of the Ain, being one of the many of the French savants that society has robbed science of. T. L.

MESSRS. PARKE, DAVIS & Co., Detroit, have recently published several interesting pamphlets. One is entitled "Cocaine in Dental Surgery;" another is a working bulletin on the drug, containing a variety of original material; and a third is a well-composed collation of what has been reported about it in home and foreign medical literature.

The same firm have devised a "cocaine case," which they sell at a moderate price, and which is ingenious and convenient.

NOTES AND QUERIES.

OBITUARY.

WILLIAM BENJAMIN CARPENTER, M.D., LL.D., F.R.S., etc., the distinguished English physiologist and author, died in London November 9, from accidental burns received from a lamp which was overturned while he was taking a vapor-bath for rheumatism. He was born in Bristol, England, in 1813; was educated there, at University College, London, and at the University of Edinburgh, where he graduated in 1839, and commenced practice in Bristol. Having resolved to devote himself exclusively to scientific and literary pursuits, he removed to London in 1843, and was soon afterwards appointed Examiner in Physiology and Comparative Anatomy in the University of London, and Professor of Medical Jurisprudence in University College. These offices he held until appointed in 1856 Registrar of the University of London. He is the author of "Principles of General and Comparative Physiology," "Principles of Human Physiology," "A Manual of Physiology," "The Microscope and its Revelations," an "Introduction to the Study of the Foraminiferæ," some able papers in the "Cyclopædia of Anatomy and Physiology," in the Reports of the British Association, in the *Quarterly Geological Journal*, and in the Philosophical Transactions. In 1861 the Royal medal was awarded to him by the Council of the Royal Society, for his contributions to physiological science. In 1868 and the two following years he took a principal part in expeditions fitted out by the English government for the exploration of the deep sea, which have yielded results of great importance to physical and biological science. It was at his instance that the "Challenger" was despatched on more extended and similar researches. His reports of these expeditions are contained in the Proceedings of the Royal Society. The honorary degree of LL D. was conferred upon him by the University of Edinburgh, 1871. He was formerly the editor of the *British and Foreign Medico-Chirurgical Review*.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM NOVEMBER 8, 1885, *TO NOVEMBER* 21, 1885.

COLONEL E. I. BAILY, SURGEON.—Relieved from duty as Attending Surgeon, San Francisco, California, and ordered for duty as Medical Director, Division of the Pacific and Department of California.

LIEUTENANT-COLONEL BASIL NORRIS, SURGEON.—Ordered for duty as Medical Director, Department of the Columbia.

MAJOR J. C. MCKEE, SURGEON.—Ordered for duty as Attending Surgeon and Examiner of Recruits, Boston, Massachusetts.

LIEUTENANT-COLONEL E. P. VOLLUM, SURGEON.—Ordered for duty as Medical Director, Department of Texas.

LIEUTENANT-COLONEL J. R. SMITH, SURGEON.—Ordered for duty as Attending Surgeon, New York City, New York.

LIEUTENANT-COLONEL R. H. ALEXANDER, SURGEON.—Ordered for duty as Medical Director, Department of Arizona.
S. O. 260, A. G. O., November 11, 1885.

MAJOR ANTHONY HEGER, SURGEON.—Member of the Army Medical Examining Board now in session in New York City, is relieved from the additional duty of Attending Surgeon in that city, to take effect when Lieutenant-Colonel Joseph R. Smith, Surgeon, shall have arrived in New York and entered upon that duty. S. O. 267, A. G. O., November 19, 1885.

CAPTAIN F. W. ELBREY, ASSISTANT-SURGEON.—Sick-leave of absence further extended six months on surgeon's certificate of disability. S. O. 263, A. G. O., November 14, 1885.

CAPTAIN JOHN J. KAM, ASSISTANT-SURGEON.—Ordered for duty as Post-Surgeon, Fort Ringgold, Texas. S. O. 141, Department of Texas, November 4, 1885.

CAPTAIN NORTON STRONG, ASSISTANT-SURGEON.—Relieved from duty at Fort Union, New Mexico, and ordered for duty as Attending Surgeon, Headquarters District of New Mexico, and Post-Surgeon, Fort Marcy, New Mexico. S. O. 171, Department of Missouri, November 16, 1885.

FIRST-LIEUTENANT C. B. EWING, ASSISTANT-SURGEON.—Now at Fort Leavenworth, Kansas, ordered to proceed to Fort Reno, Indian Territory, and report to commanding officer for temporary duty in the field. S. O. 170, Department of Missouri, November 13, 1885.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM NOVEMBER 8, 1885, *TO NOVEMBER* 21, 1885.

ASSISTANT-SURGEON J. S. SAYRE.—Detached from Naval Hospital, Mare Island, and ordered to the "Omaha."

SURGEON W. S. DIXON.—Detached from Coast-Survey Steamer "Hassler" upon reporting of his relief, Passed Assistant-Surgeon D. O. Lewis, and wait orders.

PASSED ASSISTANT-SURGEON D. O. LEWIS.—Detached from Naval Rendezvous, San Francisco, and ordered to relieve W. S. Dixon, Steamer "Hassler."

MEDICAL-DIRECTOR J. S. DUNGAN.—Ordered to Naval Rendezvous, San Francisco, to relieve Passed Assistant-Surgeon D. O. Lewis.

SURGEON M. C. DRENNAN.—Ordered to Training-Ship "New Hampshire."

SURGEON H. AULICK.—Detached from Training-Ship "New Hampshire," and wait orders.

ASSISTANT-SURGEON H. H. FITTS.—Ordered to appear before Examining Board preliminary to promotion.

PASSED ASSISTANT-SURGEON C. W. RUSH.—Granted sick-leave for three months from November 20, 1885.

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, DECEMBER 12, 1885.

ORIGINAL LECTURES.

INTRODUCTORY LECTURE ON TUMORS.

TUMORS—THEIR SUPPOSED ORIGIN—BICHAT'S GERMINAL LAYERS—COHNHEIM'S DEFINITION—DERMOID CYSTS—MONSTROSITIES—VIRCHOW'S CLASSIFICATION—INFLAMMATION—TRAUMATISM—HEREDITARY PREDISPOSITION.

Delivered at the College of Physicians and Surgeons, Chicago,

BY N. SENN, M.D. (MILWAUKEE, WISCONSIN),

Professor of Principles and Practice of Surgery and Clinical Surgery.

Reported by WILLIAM WHITFORD, M.D.

GENTLEMEN,—This morning we enter upon an obscure but exceedingly important field in surgical pathology, as I shall commence the subject of "Tumors." The origin of tumors has always furnished a fertile field for speculation and for the formulation of the most diverse hypotheses. By some pathologists they have been considered as one of the results of inflammation, while others referred them to a hyperplasia of mature tissue or to the presence of parasites; but recent investigations tend to show that they are invariably the result of superfluous deposits of immature or embryonic tissue. Upon this etiological hypothesis we shall base our remarks. In order to study the subject more intelligently, it is necessary for me to refer very briefly to the classification of embryonic tissue by Bichat, who recognizes three distinct germinal layers, which we will find constituting important landmarks in our study of the histology of tumors.

These layers are as follows: (1) the outer layer, or epiblast, which during the development of the embryo forms the cutaneous layer; (2) the middle layer, or mesoblast, from which various complicated histological elements are subsequently developed; and (3) the internal layer, or hypoblast, from which the mucous membrane and the glandular organs in communication with it are formed. Remember distinctly that the epiblastic tissue results in the formation of skin, the hypoblast forms the lining membrane of the alimentary canal and the glandular organs, while the mesoblast consists of a matrix from which are developed the more complicated histological elements, resulting in the formation of distinct organs and systems of organs.

Leaving all vague theories as to the origin of tumors, we will start out with the definition of Luecke, who describes a tumor as "an increase of volume by the production of new tissue without a corresponding physiological function." This description, however, fails to define accurately the boundary-line between different pathological products, leaving a somewhat vague distinction between a tumor proper and a swelling.

Cohnheim, the author of the hypothesis of the embryonic origin of tumors, defines a tumor to be "a circumscribed, atypical production of tissue from a matrix of superabundant or erratic deposit of embryonic elements." Under all circumstances, then, a tumor, according to his definition, is the result of tissue-proliferation from an embryonal matrix, originating from the epiblast, mesoblast, or hypoblast; but fixing the location of a tumor and referring its origin invariably to a matrix of pre-existing, latent, embryonal tissue. In adopting Cohnheim's classification, it becomes necessary for us to study some of the proofs on which are based his views and theories concerning the origin of tumors.

In the first place, I will call your attention to the development of special organs—the skin and its appendages—during the period of puberty. We know that certain organs up to the time of puberty remain, to a certain extent, in a dormant condition, not keeping pace with the general growth of the body; but when the period of puberty arrives, the genital organs, the skin and its appendages, suddenly are stimulated by a physiological impetus which results in increased tissue-growth. In pathology, the proof of this assertion is based on the fact that during this period certain forms of tumors, the result of epiblastic proliferation, develop themselves. There is no fact better established in pathology than that during the period of puberty there is an increased tissue-growth from the pre-existing epiblastic matrix, which results in the formation of dermoid cysts in localities where, from errors in embryological development, erratic deposits have taken place.

I call your attention to these cysts occurring in localities where, during the

development of the embryo, there is a liability of a misplacement of the epiblastic layer by dislocation and constriction. These cysts are found, as a rule, in regions where the epiblastic layer is liable to undergo great changes by indentation or inversion. If you will imagine with me, for example, the complicated processes of embryological development about the eye and neck, it is easy to understand how, during the indentations of the epiblast at those points for the future location of organs, an excessive inversion might occur, so that the erratic epiblast should insinuate itself into the tissues, and, by subsequent contraction and strangulation at the surface, become isolated and thus constitute a matrix in the neighborhood of the eye or neck for the future development of a dermoid cyst. This matrix is congenital; the embryonic cells remain in a latent condition until, during an increased physiological development, the epiblastic layer manifests itself at the age of puberty, which stimulates the latent cells to increased tissue-growth at that point, which will result in the formation of new tissue, and in this instance it gives rise to the formation of a cyst which contains all the elements of the epiblastic layer as we find it represented in true skin,—that is, hair, epithelial cells, and the products of secretion of the sebaceous and sweat glands, which we find in normal skin; the abnormal, erratic, epiblastic deposit simply being a matrix of immature, latent skin-structure. The same results of errors of embryological development we find in deeper localities of the body, especially where there is a blending between the germinal layers during embryonal growth: thus, we observe them in the sacral region and in the genito-urinary organs. In these localities we look for the growth of dermoid cysts during the period of puberty. Another variety of dermoid tumors we find about the neck, the result of incomplete obliteration of the fœtal remnant of the branchial tracts. These tumors, then, in the true sense of the word, are always congenital, inasmuch as the child is born with the matrix, which, during the increased physiological development of the epiblastic layer, results in the production of the histological elements of which the skin and its appendages are composed.

Another familiar example, substantiating the theory of the embryonal origin of tumors, we find in the pregnant uterus. As a rule, hypertrophy of tissue is produced and attended by increased physiological function. In the gravid uterus there is an increase of muscular tissue attending simply an increased physiological growth of an organ unattended by muscular contraction. How can we explain this increase of muscular tissue? During pregnancy the muscular fibres remain inactive; the uterus is engorged by an increased afflux of blood. We can only explain the attending muscular hyperplasia by assuming the presence of a superabundant deposit of embryonal cells awaiting a favorable opportunity to develop themselves into mature muscular tissue. It is not an increased activity; it is simply an increased physiological production, the development of new muscular elements from embryonal deposits, the uterus preparing itself in that way for future increased action.

Another familiar instance can be mentioned in connection with certain monstrosities (superabundant organs), which can only be satisfactorily explained by assuming that, during the period of development, at certain points there is an increased production of embryonal tissue which keeps pace with the physiological development of the body. In children born with six fingers instead of five, it follows as a necessary consequence that the supernumerary member was the result of an abnormal additional production of embryonal tissue. Monstrosities, again, are peculiar from the fact that, instead of an increased production of embryonal tissue, we observe cases where there is a lack of tissue-development from a deficiency in the pre-existing embryonal deposition, which results in a corresponding defect or absence of certain organs. Another instance where this hypothesis is well demonstrated is furnished by the so-called giant-growth, both general and local. Giants nowadays are not frequently seen, and the question arises, What is the difference in the development between an ordinary man and a giant? Giants are always born giants, although at the time of birth the size of the child may not be in excess. We have in that child a superabundance of embryonal tissue-deposits, which enables the body to develop subsequently to an unusual extent. Children are sometimes born with inequality of symmet-

rical limbs: one limb is larger than the other at the time of birth, giant-growth taking place during intra-uterine life. Friedberg observed a case where, in a female child at the time of birth, the right leg was considerably larger than the left; after birth, symmetrical development failed to take place, and the larger limb assumed giant-growth, which induced Friedberg to assert that giant-growth is not only congenital, but progressive. If the embryonal deposits are there latent, slumbering, giant-growth may take place at any subsequent period during life, awaiting a favorable opportunity until an increased afflux of blood to the part results in increased tissue-proliferation; the difference in the growth in the two limbs being due to the amount of primary deposit of embryonal tissue.

A tumor is invariably an integral part of the organism: it is not a new formation. It consists in the growth and development of pre-existing tissue-elements. In cases of dermoid cysts in man we never find heterologous structures; we always look for the products of normal tissue-proliferation. We never expect to find anything in a dermoid cyst that is not found in the normal body. While we expect in such instances to find hair or the products of epithelial proliferation and degeneration, we never find feathers or any other heterologous tissues; while in birds, when dermoid cysts arise, we find no hair, but invariably feathers: so the products of a displaced epiblastic matrix always represent normal tissue-elements in an abnormal place.

The law which governs the blood-supply of a tumor is a subject which remains to be explained by future research. All that I can tell you is that the normal supply of blood to the tissues of the body is adequate for the development and growth of a tumor. The vascular supply takes place in the same manner as during the physiological production of new tissue, as we observe it during the growth of the body or the regeneration of tissues after injury or disease, and consists simply in a development of new, or increase in size of pre-existing, blood-vessels. The vascularization of the tumor is simply a development of blood-vessels adequate to the demand of increased tissue-proliferation. The nerve-supply of a tumor is a still more important subject, and one, I may say, which is still wrapped in a great deal of obscurity. While we observe a development of increased tissue-growth independently of innervation from the cerebro-spinal axis (as in cases, for instance, of physiological development of the gravid uterus in animals where the spinal centre has been destroyed), it would appear that increased tissue-proliferation in a growth can and will result without an increased supply of nerve-elements. The study of the lymphatic system in tumors has not received the attention the importance of the subject merits. It still remains to be demonstrated by careful injections whether in certain kinds of tumors there is an increased or diminished development of the lymphatic system. The growth of a tumor depends primarily upon the amount of embryonal tissue deposited; and, secondarily, it is influenced and regulated by the amount of arterial blood supplied to the part, the tissue-growth being amenable to the same laws as govern the physiological growth and development of the body. If, by any means, either from the anatomical structure of the part, the blood-supply be scanty of the area in which the tumor grows, or local anæmia follow as the direct result of some pathological conditions, either by causing obstruction in the vessels or on account of the blood being diverted to a different part not in the immediate vicinity of the tumor, the growth of the tumor will be correspondingly slow. If, on the other hand, the tumor develop in a vascular tissue, or if the increase of arterial supply be favored by the development of additional pathological conditions in the immediate vicinity of the tumor, you would naturally expect increased tissue-growth in the tumor itself.

The retrograde changes in a tumor depend almost entirely upon its blood-supply. As long as the vascular supply can keep pace with the increased tissue-growth, just so long will the histological elements of which the tumor is composed multiply themselves. If there is an anæmia, pre-existing in the tumor or artificially induced by the production of pathological conditions which diminish the blood-supply, we may expect a retrograde transformation of the tissues *pari passu* with the diminution of the circulation. The retrograde changes most frequently observed are fatty degeneration, tyrosis, calcification, myxoid and colloid degeneration, the existing

tissue-elements undergoing a retrograde metamorphosis as the necessary result of diminished nutrition.

In differentiating between a swelling and a tumor, consider carefully the component parts of which the new formation is composed. If the swelling of an organ be the result of increased blood-supply, if it follow an acute or subacute inflammation, and be due to an increase in connective-tissue proliferation, we are dealing with a swelling, and not with a tumor from an embryonal matrix. If a tumor is never capable of performing a physiological function (in which all pathologists are agreed), an increase in the volume of an organ resulting from an increase of pre-existing normal histological elements, and attended by an increased secretion or function, is invariably a swelling and not a tumor. Again, if we have from any cause an obstruction to the exit of a physiological secretion, resulting in a distention of a pre-existing space, the swelling is a retention-cyst, and not a tumor. Such a cyst we call a retention-cyst in contradistinction to another variety of cysts, cystoma, as it simply consists in a distention of a pre-existing cavity by the accumulation of the normal physiological secretion of the part; while a tumor, on the other hand, invariably means a production of tissue-elements from pre-existing embryonal cells.

A hæmatoma, for instance, we would not call a tumor, although we find it so designated in many works on surgery, because a hæmatoma simply means an extravasation of blood into the tissues,—in other words, an accumulation of pre-existing, mature, morphological elements in the tissues. In like manner, a hydrocele is not a tumor, as the swelling results from exudation and accumulation in the serous sac of the tunica vaginalis, and is not a new formation from embryonal tissue. The term tumor, then, invariably implies an increase in volume by tissue-proliferation from an embryonal matrix.

We now come to the important subject of the

CLASSIFICATION OF TUMORS.

I will call your attention, in the first place, to the classification of Virchow, who arranged all tumors into three distinct classes, on a supposed anatomical and physiological basis. Under the name of *histioid* he included all tumors which were supposed to consist of one histological tissue-element; the second class he denominated *organoid*, on the ground that the tumors belonging to this class were composed of organs from a combination of histological elements; thirdly, the name *teratoid* included all tumors which contained a more or less perfect system of organs. Let us see if this classification will stand the test of criticism. A histioid tumor composed of only one histological element, except in cases of very minute epithelial tumors or fibromata, is an impossibility. If we have an epithelioma developing upon a mucous or cutaneous surface, it is only a histioid tumor as long as the pathological product is limited to an abnormal production of epithelial cells, but as soon as the cells have passed beyond their physiological boundary-line there is a corresponding increase in all the tissues of the part. On the other hand, an organoid tumor, no matter how perfect it may be in its anatomical structure, is always devoid of any physiological function. Anatomically, it may be perfect; physiologically, the product is invariably sterile. A teratoid tumor presents at the best only a combination of imperfect systems, which are anatomically incomplete and physiologically of no importance.

Remaining true to our hypothesis that a tumor is invariably the result of pre-existing embryonal tissue-elements, we will adhere closely to the histological structure of the part in which tumors are found, and adopt the classification of Cohnheim, who under the head of the connective-tissue type of tumors includes the following: fibroma, lipoma, myxoma, chondroma, osteoma, glioma, lymphangioma, lymphoma, and sarcoma,—tumors which grow from a matrix of embryonal connective tissue. A tumor belonging to this class, whether benign or malignant, is invariably the product of tissue-proliferation,—not from pre-existing, mature connective tissue, as we find it when it results from inflammatory processes, but as the product of tissue-growth from a pre-existing embryonal matrix. The second class embraces all tumors which are derived from the epiblast or hypoblast, represented by papilloma, epithelioma, onychoma, struma, cystoma, adenoma, and carcinoma,—which arise from a superabundant or erratic deposit of embryonal tissue: in other words,

the epithelial type represents all tumors which originally developed from a pre-existing embryonal matrix derived from the epiblast or hypoblast. A third class includes the myomata, with the varieties myoma stricellulare and lævicellulare,—that is, tumors which contain striped or unstriped muscular fibres.

Passing to the nervous system, we find that it furnishes the soil for the fourth class of tumors, the myelinic neuroma, the neuro-fibroma, and the glioma,—glioma being the result of connective-tissue proliferation in the neuroglia of the nerve-centres and the retina. You will readily understand that these four classes, based strictly upon a histological basis, represent the first two divisions according to the classification of Virchow, while the fifth, and last, class includes all the remaining tumors, which have been designated teratoid tumors by Virchow. In this class of tumors we may find all the elements resulting from a proliferation of the epiblast, hypoblast, and mesoblast; in other words, compound tumors which contain hair and the products of glandular secretion, as skin and its appendages, in cases of dermoid cysts, while others contain more complicated structures, as bone, teeth, cartilage, muscle, brain-tissue, nerves, and occasionally portions of the intestinal canal with its glandular organs. You will recollect that we defined a tumor as "an atypical production of tissue," both in the malignant and benign forms. Now, by the term "atypical" I mean the existence of heterologous or erratic tissue-elements, the term first being introduced by Waldeyer for the purpose of drawing a line of distinction between malignant and benign growths, assuming that cancer was an atypical development of epithelial cells, the result of penetration of these tissue-elements into the subjacent connective tissue where they normally do not exist. We go one step further, and apply the term to all forms of tumors. You will readily understand why: because we have taken it for granted that a tumor does not develop from mature tissue, but that it is always the result of tissue-proliferation from pre-existing, latent, embryonal cells,—cells which take no part in the normal physiological function of the part, but cells deposited during embryonal life, remaining latent, simply awaiting a favorable opportunity to develop themselves into a tumor. If a tumor, malignant or benign, grow from such a matrix, its cellular elements are always atypical. The difference between a papilloma and an epithelioma simply consists in the fact that in the former the epithelial cells occupy their normal, physiological, and legitimate position, and the tumor remains benign just so long as there is no relative change of position between the epithelial cells and the subjacent tissues. On the other hand, in carcinoma, epithelial cells are found where normally they do not exist. If, for example, in a gland of the skin there is an increased production of epithelial cells and there is no infiltration of the subjacent connective tissue, we may be satisfied that the tumor is not malignant.

There is, however, anatomically, such a thing as a non-malignant stage of cancer, in spite of its very name. In the early stage of epithelial tumors we find simply a superficial increase in the thickness of the epidermic layer,—that is the stage when the cancer still remains as a non-malignant growth; but just as soon as the physiological boundary-line between the epithelial layer and the subjacent tissues is destroyed, in other words, just as soon as epithelial elements are found in places where they have no legitimate existence, we have to deal with a cancer. The origin of tumors from erratic or superabundant deposits of embryonal tissue is the only explanation that pathology can offer why a cancer may develop in parts of the body where, normally, epithelial cells do not exist. Competent pathologists have claimed that cancer can develop only in parts normally supplied with a matrix of mature epithelial cells, while others assert that cancer has been found in parts where no epithelium can be found in a normal condition. How shall we explain this discrepancy? We offer a simple explanation in the fact that during the development of the fœtus the epiblast or hypoblast may have become displaced somewhere by an error of development, and that these epithelial cells have remained dormant until certain conditions favorable to their development should have given rise to tissue-proliferation from this embryonal matrix and the formation of an epithelial tumor. In cases of benign growth our definition holds good, inasmuch as we can in no way explain, either

from an anatomical or physiological standpoint or by way of experiment, the development of pre-existing mature tissue-cells into a tumor. The most tangible and logical explanation for the growth and development of tumors is furnished by the hypothesis that the tissue-elements of a tumor, benign or malignant, are always produced from a matrix of embryonal tissue.

In considering the exciting causes, let us pass in rapid review the effect of inflammation. Formerly, pathologists supposed that inflammation might result in the formation of a tumor; we, on the other hand, deny *in toto* the possibility of such an occurrence independently of the presence of more essential conditions. Inflammation may act simply as one of the exciting causes. If we assume that at some point we have a deposit of embryonal tissue awaiting increased vascular supply, it will furnish the necessary blood-supply for tissue-growth to take place. It may, however, favor the development and growth of a tumor in another way by producing a reduction in the normal physiological resistance in the tissues, of which we shall have more to say hereafter in discussing the conditions which are necessary to establish malignancy.

Traumatism has generally been claimed to be, in the majority of cases, one of the principal elements in the causation of tumors. We shall simply consider it in the light of an exciting cause by inducing pathological conditions favorable to tumor-growth. The statistics of Dr. Boll, collected with a view to prove the traumatic origin of cancer, show that of a large number of cases only about twelve or fourteen per cent. were traceable to this cause. Traumatism is never the essential and only cause of tumor-growth: it acts as an exciting cause by inducing inflammation, which we have mentioned as a cause favorable to growth of abnormal tissue. Prolonged irritation—pathological, mechanical, chemical, and thermal—favors the development of a tumor when acting upon a part inhabited by a deposit of embryonal tissue; but when this essential factor is absent they may result in pathological changes of various kinds, but must always fail in producing a tumor. A true tumor is neither infectious nor contagious. No surgeon has ever infected himself in operating, and all transplantations of tumor-tissue in animals have so far proved failures. The transplanted tissue may grow for a few days or weeks, when tissue-growth is arrested and the product is invariably removed by absorption.

Gastric disturbances and mental anxiety are frequently mentioned as causes of cancer, but they simply favor tumor-growth by modifying the circulation. If our hypothesis prove correct, all influences which impair the general health of the patient are incapable of transplanting embryonal tissue into the body; consequently, they are only conditions which favor tissue-growth by modifying the circulation on the one hand, and by diminishing the physiological resistance of the tissues on the other, thus acting as exciting causes in stimulating the latent cells to active proliferation. Hereditary predisposition we recognize as the principal element of the causation of tumors by assuming that a child is invariably born not with a tumor necessarily, but with a matrix from which the tumor subsequently develops itself. It is a well-recognized fact that malignant as well as non-malignant growths can often be traced to a hereditary predisposition. This predisposition does not imply that the tumor itself is congenital. All that is required is to have a matrix which is congenital, and then, by future changes which favor the development of tissue-proliferation from that matrix, the tumor is developed. The term congenital in this connection means a storage of embryonal tissue at a point from whence subsequently the tumor springs,—that is to say, the embryonal tissue-elements have been in excess or have found their way to an abnormal place, and constitute the necessary germs from which the tumor develops subsequently. Physiological growth, traumatism, inflammation, and all conditions which modify the circulation or impair nutrition, simply act as exciting causes.

In considering the influences which determine the location of tumors, there is no exception to the rule that tumors are most frequently met with in localities where during embryonal life the most complicated cell-growth is observed. This assertion is well founded, by the fact that malignant tumors have their favorite locations at the junction of the skin with the mucous membrane,—a point in the embryo where we have a blending of tissue from the epiblast, the mesoblast, and the hypoblast. For this reason, and no other, epithelial

cancer is found most frequently where the mucous membrane blends with the skin.

Chondroma never results from proliferation of mature cartilage-cells; it is invariably the result of development of tissue from immature or erratic cartilage-cells. Virchow called attention to the fact that frequently chondroma of the femur has its origin in the interior of the bone from a deposit of cartilage-cells, remnants from embryonal life.

To illustrate the difference between tumors and inflammatory swellings, let us briefly consider the enlargements of the cervical glands as they present themselves to the surgeon. We may have an enlargement of the glands from adenitis, but in this instance the swelling is caused by an exudation of the morphological elements of the blood or proliferation of pre-existing mature connective tissue, consequently it cannot be called a tumor. If the swelling be the result of a specific infection, the inflammation will give rise to specific inflammatory products, as we observe it in cases of tuberculosis and syphilis, the results of inflammation produced by the deposition of specific germs in the gland-tissue; on the other hand, enlargements which result from proliferation, not of pre-existing mature elements, but of latent embryonal deposits, are true tumors, and in this particular locality they are represented by lymphoma, lymphangioma, and sarcoma.

ORIGINAL COMMUNICATIONS

NOTES OF FOUR CASES OF EYE-INJURIES.*

BY A. FRIEDENWALD, M.D.,

Professor of Diseases of the Eye and Ear, College of Physicians and Surgeons, Baltimore.

ALTHOUGH injuries to the eye are quite common in the experience of the specialist, the cases which I shall relate may prove not uninteresting to this Society, which is in the main composed of general practitioners.

Case I.—H. N., æt. 27 years, tinner, applied to me October 18, 1885, having been struck upon the eye with a piece of sharp tin while at work about a week before. He had suffered from pain almost uninterruptedly since the injury. His sight was greatly impaired immediately after the mishap, and, according to his statement, he had not been able to see anything at all from the day after up to the time of coming under observation.

On examination I found that he had only perception of light. The conjunctiva was intensely hyperæmic, the pupil widely dilated, the anterior chamber extremely shallow; the lens was opaque and swollen, and it had pushed the iris forward, and induced a high degree of intraocular pressure.

Experience teaches that this cannot be tolerated with safety for any length of time. If permitted to continue, we must expect a disastrous form of inflammation to follow, and this, together with the continued increased tension, will not only deprive the organ permanently of the visual power, but probably also leave it in an unsightly condition, and possibly in a condition that may prove inimical to the sound eye.

October 18. Having ordered opiates and other palliative treatment temporarily, I proceeded to remove the injured lens, which is the only means by which we can hope to give relief in these cases. I made a downward corneal incision with a keratome, about three lines in length, just within the pupil. The narrowed anterior chamber made a more peripheral incision almost impossible. I next placed a Daviel's curette on the lower lip of the incision, and with very slight pressure readily evacuated the whole of the injured lens.

The patient experienced immediate relief from the operation, and, although the opiates were discontinued, the pain which he had so bitterly complained of did not return. There was not the slightest untoward symptom observed during the after-treatment, and the patient was discharged in ten days with as good sight as is possible without the lens.

Case II.—P. H., æt. 27 years, oyster-shucker, presented himself for treatment on September 13, 1885, having received an injury in his right eye, while at work, about three days before. I found an irregular abrasion occupying the centre of the upper and outer quadrant of the cornea, about two lines long in its longest and about a line and a half in its shortest diameter; conjunctival hyperæmia moderate, and pain of a subdued character. Ordered atropine, and applied iodoform once daily.

* Related at the meeting of the Baltimore Medical Association, November 10, 1885.

During the first few days the corneal wound presented very little change; after which time, however, a slight suppuration manifested itself, and in the course of about a week the corneal disease had assumed the character of a serpiginous ulcer. This form of ulceration, first described by Saemisch, has the peculiarity of showing no great tendency to extend very deep in the cornea, but must be dreaded for its superficial extension over a large part of its surface, while the parts primarily affected cicatrize and leave very marked opacities behind. The continued use of iodoform did good service in this case, and brought it to a comparatively favorable termination in about three weeks.

The chief point of interest to be noticed in this case, besides the good result attributable to the iodoform, is the peculiarity of the agent through which the injury was inflicted. Oyster-packing being a very extensive branch of industry in our city, we have many opportunities to observe how exceedingly damaging a stray piece of oyster-shell is apt to prove. The subsequent trouble to be expected from a corneal abrasion received in this way is almost invariably out of proportion to the primary lesion. Such an injury is almost certain to assume a suppurative form of inflammation, and to involve a considerable part of the cornea contiguous to the original seat of injury. From the course of such injuries we are warranted in believing that, in addition to the mechanical effect, there is a septic influence at work to which the principal damage must be attributed.

Another very interesting point in connection with the case presents itself on examining the sound eye. Here is seen an irregular pupil, drawn towards a cicatricial line located in the upper margin of the cornea. His sight is perfect with this eye. On referring to my note-book, (having recognized in his name a former patient), I found that he received an injury on December 25, 1868, when he was ten years old. The accident occurred immediately after the discharge of a pistol in the hands of a young companion. Having gone out against the wishes of his parents, he tried to conceal from them the injury that he had sustained, to avoid punishment for his disobedience. When he could no longer succeed in this, he endeavored to suppress his suffering in their presence, in consequence of which medical aid was not sought till about three weeks from the date of the injury, when the long-continued pain had caused considerable constitutional disturbance. At this time I found a cicatrix at the upper and inner part of the cornea, and in the iris opposite I saw a shining foreign body which I took to be a piece of a percussion-cap.

On January 16, 1869, I made an incision in the sclero-corneal junction, and with an iris-forceps grasped the iris and the foreign body embedded in it, and, after withdrawing it, removed it with the scissors. All the troublesome symptoms disappeared from this time, and I had the satisfaction, after seventeen years, to find that the relief was permanent.

Case III.—Mr. H., aged 20, assistant to the Professor of Chemistry at the Baltimore City College. Was called by his medical attendant to see him on October 4, 1885, for an injury sustained in both eyes about four or five days before. The mishap arose from an explosion occurring in the manufacture of oxygen from potassium chlorate, mixed with what was at the time thought to be oxide of manganese, but which afterwards proved to have been powdered charcoal.

On examination, I found the right eye to have escaped serious damage. There was considerable conjunctival hyperæmia, but otherwise there was nothing to be found to cause alarm. He could not bear the light well, and the visual tests could not be very thorough; but I soon satisfied myself that the sight in this eye had not been injured.

The left eye presented a much more threatening aspect. At a point about a line and a half from the corneal margin in the inner part of the sclera, corresponding very nearly with the horizontal meridian, was seen a blackish mass about twice the size of a pin's head, which evidently had buried itself deeply in the tissues beneath. Only quantitative vision had been maintained. The pain of which the patient complained was referred specially to the eye, while pain about the brow and temple was only occasional, of short duration, and not excessive in character. The lens appeared intact, but there was a grayish reflex from the lower and outer portion of the vitreous. The ophthalmoscope failed to furnish any reflex from the

fundus oculi; the whole of the vitreous was cloudy. I had very little doubt that a part of the mass, a sample of which was still fixed in the scleral wound, had entered the vitreous. Palliative treatment was resorted to, and in the course of about a week all the active symptoms had disappeared. At this time a slight improvement in vision was observed. On holding the hands downward and inward, the fingers could be dimly seen. This slight improvement lasted but three or four days, when the condition relapsed to that previously described, in which state it has continued up to the present time.

The patient being entirely free of pain, and the eye presenting no abnormal appearance, casually examined (barring a small black spot seen where the lesion took place), had induced me to decide not to sacrifice the organ, although I fully recognized that it must be accepted as a rule that when a foreign body has entered the interior of the eye, not only is that eye doomed, but there is constant danger in store for the sound one. The peculiar character of the foreign body in this case, and the entire absence of symptoms, however, led me to hope that the injured eye will not endanger the sound one, and, as the patient can be kept under close observation, the attempt to preserve the injured eye seemed to me justifiable.

Case IV.—C. H., æt. 7 years, was struck in the left eye on June 1, 1885, with an oyster-shell. The examination revealed a cut through the cornea, about a line from its summit, extending into the sclera slightly to either side, presenting an appearance similar to that furnished by an incision made for cataract-extraction. At the inner end of the wound the iris had prolapsed. The anterior chamber was entirely filled with blood, and this prevented me from estimating to what degree the eye had really been injured, as the parts beneath were completely hidden by the accumulated blood. The pain at first was very great, but this soon yielded to the palliative treatment instituted. The treatment consisted of atropine, a protective bandage, and complete rest in bed. In about a week after the injury the anterior chamber was free from blood, notwithstanding which, however, sight had not returned, although the lens had been left intact. The wound had healed kindly, and the patient complained of no discomfort.

June 29. Prolapse very slight; ophthalmoscope gives no reflex from the fundus; no vision.

July 6. Begins to see; can count fingers at three or four feet.

July 8. Condition the same.

July 16. Can read letters of No. 8 Snellen at reading distance.

The vision constantly improved till September 22, when he read fine print readily. In the mean time, however, the inner end of the wound, where the iris had been incarcerated, had assumed a slight staphylomatous condition.

The chief interest in this case is the very good result obtained, not only in consideration of the extent of the lesion, but principally on account of the dangerous character of the weapon by which the injury was inflicted. In connection with our second case, I pointed out the danger which is to be dreaded from corneal wounds inflicted by oyster-shells. We are therefore warranted in regarding the termination in this case as an exceptionally favorable one, and are encouraged thereby not to give up all hope, even after very extensive lesions.

A CASE OF OPIUM-SMOKING.

BY J. B. MATTISON, M.D.

OPIUM-ADDICTION having its origin in a medical use of the pipe is rare. In a paper by the writer* it was asserted that cases due to a legitimate necessity, inasmuch as this therapeutical method is so limited, must be seldom or never met with. In an experience embracing the history of many habitués, no exception to this statement has been noted.

One case, however, under our care the past year, in which the form of addiction was smoking, though not caused by that, had some features that may make its recital of interest.

Mrs. A., æt. 23, married at an early age, and became the mother of two children. After the birth of the second, in 1879, she was given morphine by her medical attendant to secure sleep, and, unaware of its harmful nature, used it at irregular intervals for a year. It had then become a necessity, and was continued in daily doses of two one-eighth-grain pills at bedtime until April, 1883, when she

* "The Genesis of Opium-Addiction," *Detroit Lancet*, January, 1884.

began using the pipe at the suggestion of a friend, who commended it as preferable to the drug by the mouth.

At first, smoking was done only at bed-time, but, as usual, the demand for a more frequent supply becoming imperative, the intervals lessened until she would sometimes go without food, smoking and sleeping the twenty-four hours round.

At the time of coming under our care she was smoking only three times a day, using an unknown amount of opium, and at times increasing its effect, if occasion required, with the crude drug by the mouth.

Physical examination showed no impairment of renal, ovarian, or pulmonary functions, but the heart's action was feeble, frequent, irregular, and intermittent. Bowels torpid, appetite poor, skin pale, and memory much impaired. Albumen, sugar, and casts were absent; sp. gr. was 1018.

The pipe was at once discarded, and two grains of morphine per diem given by mouth. This proved more than enough, and was soon decreased to one grain daily; and then very gradual reductions made, averaging about one minim of Magendie daily, with generous diet and full doses of tincture of iron and nux vomica.

The new taking, with this roborant regimen, speedily brought a change for the better. Strength and appetite, notably the latter, markedly increased, and the patient's condition in every way much improved.

The opiate-quitting was attended with little reflex irritation, the most prominent being headache, not specially severe, forty-four hours after entire withdrawal. This was promptly removed by an injection of morphine, and did not return. Alvine relaxation was more marked than usual, the maximum movements in one day being ten, and then a daily decrease. No astringent was given. Vomiting occurred but once, and only one meal—evening of headache—was omitted. Patient was about each day.

The therapeutics of the case included tonics noted, daily faradic séances, morning cold shower-baths, occasional one-grain injections of cocaine to relieve fatigue or muscular aching, and fluid extract of cannabis indica to secure sleep.

The patient's need for a hypnotic ended on the tenth day. The approach of her periodical function was attended with severe pain, to relieve which hot sitz-baths, with fifteen to twenty minims of tincture of camphor, and one-sixtieth grain of atropia hypodermically, were used with success. Under this treatment she progressively improved, added nearly twenty pounds to her weight, and was dismissed recovered,—looking well, feeling well, and promising to do well.

Two or three points in this case may be briefly noted. While, in the author's method,* reliance is largely placed on bromide of sodium as a controller of reflex disorder incident to the opiate-disusing, cases sometimes present in which it is not needed. Three such have been under our care the past year: one, a lady, of short addiction, and the daily taking small; another, a gentleman (commended to us by Roberts Bartholow), several years given to morphine subcutaneously, whose physical condition was so reduced that it was contra-indicated; and the present case, in which the peculiar form of addiction led us to think the reflex irritation following withdrawal would not, as the sequel proved, be very decided. All these patients recovered.

More than the ordinary degree of alvine disturbance attended this case. Whether this were due to the lack of preliminary sedation secured by our usual giving of the bromide, or dependent upon peculiarity of the patient, is uncertain. Probably the former had more to do with it, inasmuch as an equal relaxation with the bromide is rare.

As a rule, the periodical function in smokers is not suspended. The reverse obtains in most habitués other than of the pipe. In this case, after the opiate-quitting it was unusually active, and with pain. In our experience, special treatment seldom has been called for, but, when demanded, camphor in full doses and atropine hypodermically—the latter especially commended by Anstie in peri-uterine neuralgia—served us best. Cannabis indica, as usual, proved an efficient hypnotic. Forty minims of Squibb's extract was the maximum amount required.

Opium-smoking, as a vice, has made and is making progress in this country. Law may limit it, but not until public opinion has reached the point of regarding the use of opium in any form, save to avert or control disease, as always and only an evil,—subversive of health of both body and mind,—and that, as has been well observed by recent foreign authority, "there is no such thing as moderation for habitual or even occasional employment of opiates outside of medical practice," but that the inevitable tendency is for the demand to grow by what it feeds on until it overmasters all self-effort at escape; not, we say, until laymen and doctors alike appreciate these

* "The Treatment of Opium-Addiction," Putnam's Sons, New York.

truths, and by precept and practice enforce them, can we hope that this growing evil will decline.

Opium-smoking is not likely to take high rank as a therapeutic factor. It is too cumbrous for general use, and its medical range too limited. True, it has been so advised, Dr. Thudichum* commending it in colds, hay-fever, neuralgia, etc., and asserting no danger of addiction, only those having incurable disease being unable to resist that result.

As to its remedial value, there is no question that it is much inferior to other opiate methods, and this, with added objections, supports an editorial opinion of the foreign authority mentioned,† in which, referring to the suggestion that medical men avail themselves of the pipe as a therapeutic agent, it was asserted, "We feel sure we represent the bulk of medical opinion in repudiating that suggestion."

As to no risk of addiction from smoking, that is a mistake. No form of frequent opiate-taking is free from that hazard, and the pipe especially has for many a peculiar fascination that soon makes them powerless to resist.

On the other hand, as compared with morphine hypodermically, we believe its effects, if not used to excess, less disastrous and more easily overcome, and that if an opiate be imperatively required,—from incurably painful disease or confirmed addiction,—smoking, if meeting the demand, is often better than the syringe.

304 State Street, Brooklyn.

NOTE ON THE USES OF LOBELIA INFLATA.

BY V. M. REICHARD, M.D.

LOBELIA may be used internally as a nauseant, an expectorant, an emetic, and as an antispasmodic. As a nauseant, it should be given in small doses frequently repeated. If the stomach be decidedly acid it may be very distressing: so it is safer always to administer it with a little bicarbonate of sodium. In the first stage of acute bronchitis, combined with an opiate, as paregoric, it is unexcelled. It relieves the fulness and pain, and promotes a free flow from the bronchial mucous membrane. In children troubled with a nocturnal cough and tightness of breathing, there is nothing better than tincture of lobelia in small doses. When given as an emetic, it is a good plan to give about ten drops in a wineglassful of warm water every fifteen minutes; or, with small children, give small doses and put them into a hot bath at the same time. The text-books say it is too depressing as an emetic, but I must say that, observing the precautions above mentioned, I have not found it so. In asthma, it will break up an attack at once if pushed to emesis. As an antispasmodic, especially in nervous exaltation, it is a remedy of great utility. An attack of hystero-epilepsy or of any hysterical manifestation will be cut short by it. If the patient cannot or will not swallow, it may be given by enema or hypodermically. After one or two trials of the drug, the patient will forego the hysterical attack rather than submit to the nausea. In this way I have relieved hysterical epilepsy, hysterical aphonia, and many more of the hysterical manifestations.

While it will not always cure the habit, it will relieve the symptom which so much disturbs the friends of the patient.

As a local application it has an extended use. Its value is undoubted, and, so far as I know, this is not mentioned in any of the standard text-books on materia medica. As a wash for indolent sores, as an application to traumatic erysipelas and to incised wounds, I have never found its equal. In the latter class of injuries it is especially useful. It acts as a hæmostatic and astringent. Its best application is to those wounds the edges of which can be brought together.

In any incised wound, no matter how large, or how great the hemorrhage, so long as it does not require a ligature, if the edges be brought together and held for a few minutes while a pledget of cotton wet with tincture of lobelia is applied, the hemorrhage will cease, the parts will adhere, and all will be prepared for union by the first intention. Though lobelia may not be a germicide, yet it will so entirely close up a wound as to render it perfectly aseptic. It is no longer a matter of experiment with me, but a fixed conviction, the result of observation of a great number of cases, varying from a mere scratch to severe incised wounds. In one case, a man while butchering, by a slip of the knife, cut a gash into the back of the hand

* Schmidt's Jahrbücher, 1884; New York Medical Record, September 20, 1884.

† British Medical Journal, October 17, 1885.

and the arm, beginning in the web of the thumb opposite the metacarpo-phalangeal articulation, running diagonally upward and towards the radius, extending in front about two inches above the wrist-joint. Where the knife entered the wound was quite deep, dividing the first and second extensors of the thumb. The radial artery was barely missed, and was seen pulsating in the bottom of the wound. The hemorrhage was so severe as to lead for a moment to the belief that the radial had been divided. The man positively refused to have the divided tendons sutured. The hand was put on such a splint as would support the thumb in its place, the edges of the wound approximated with adhesive strips, and the parts covered with absorbent cotton wet with a saturated tincture of lobelia. In three days union was apparently complete, but the perfection of the result was marred by the imprudence of the patient, who took off the splint and used the hand, with the result of destroying the union over the site of the divided tendons.

Any one who will try this remedy in the class of cases indicated cannot fail to be satisfied with the result.

The stigma cast upon lobelia by irregular practitioners claiming for it specific properties has caused it to be too little used by regular physicians. The remedy deserves more notice at our hands. While casting around for *new* remedies, it is proper to investigate fully the properties of those we already have. Though the active principle may be poisonous, there is not sufficient of it in a medicinal dose of the tincture to be dangerous. In a series of experiments made to determine the toxic character of this drug, I found it *impossible* to kill the animals experimented upon. Heroic doses were given to half-grown cats, with no other effect than intense nausea and weakness for a day or two. In no case would it kill, though as much as two ounces of a saturated tincture of the seed were given in the course of an hour.

FAIR PLAY, MARYLAND.

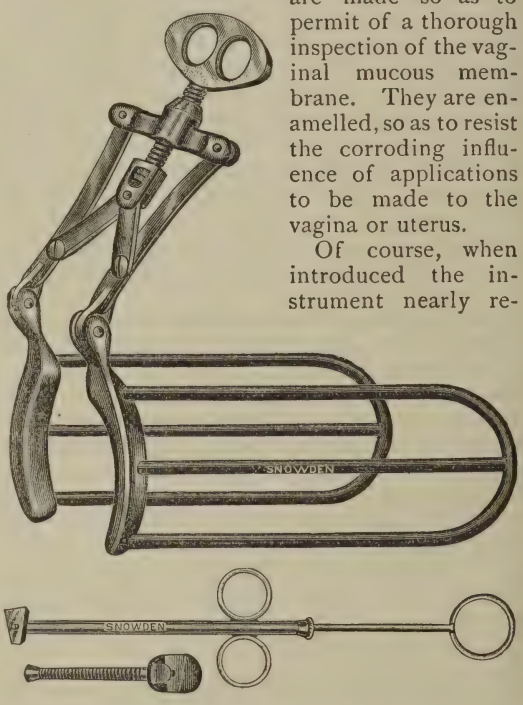
DR. WILLIAM B. ATKINSON has been appointed Special Inspector for the Delaware District of the State Board of Health of Pennsylvania.

TWO NEW INSTRUMENTS.

BY J. M. KEATING, M.D.,

Visiting Obstetrician to Philadelphia Hospital, and Lecturer on Diseases of Women and Children, etc.

I HAD recently made for me by Mr. Snowden, of this city, a form of vaginal speculum which I think has some points that will make it an available and valuable instrument to the general practitioner. As will be seen, it is a bivalve speculum, made so as to combine the greatest possible strength with the minimum weight. The instrument is adapted from Fränkel's nasal speculum. The blades are made so as to permit of a thorough inspection of the vaginal mucous membrane. They are enamelled, so as to resist the corroding influence of applications to be made to the vagina or uterus.



Of course, when introduced the instrument nearly resembles the ordinary bivalve speculum, the blades closely approximating. After sufficient dilatation has been accomplished to stretch the vagina thoroughly and bring the cervix in full view, the *mechanism* can be turned upward, on the hinge, upon the pubes or beneath the coccyx, and thus the vagina kept opened without the necessity of an assistant.

The second wood-cut represents an elastic intra-uterine pessary, which I think will prove useful in certain conditions.

It is formed of spiral wire, with an opening through its entire length. When in-

troduced into the uterine canal it will, of course, follow any curve that may exist, and will then straighten itself with gradual, persistent pressure, not sufficient to tear adhesions abruptly. In this way the condensed tissue in the crease of long-standing flexions will be made to expand gradually and the obstructed fluid-channels resume their functions; slight adhesions will be overcome.

There is another advantage which is possessed by this instrument,—that of being readily converted into a uterine repositor. By means of the attachment, which is easily made, a probe-pointed bar is passed by the thumb through the canal of the instrument, and in this way, if the instrument be in a flexed uterus, it can be straightened with just as much force as the operator chooses to use.

The tube with the bar and spring can then be detached, and the pessary allowed to remain in position; and if it is desired to convert it into a non-flexible one, a smaller bar of steel can be run through the canal of the instrument and permanently held by a screw-thread.

I have had these stems made with the button which rests upon the uterus of hard rubber, turned at the end in a flap or lip. The object of this is to catch the cotton tampon and hold it in place, and thus correct versions of the womb by this leverage. The stem can be kept at any angle to the vertical plane of the pelvis by the amount of cotton in the tampon which is caught and held by this arrangement.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

BACILLUS TUBERCULOSIS IN THE SPUTA OF AN INDIVIDUAL AFFECTED WITH GRINDER'S CONSUMPTION.

PROF. DA COSTA brought before his clinic, on the 14th ult., a man but little past middle life, who had been for many years constantly engaged as a grinder of tools, and had lived in an atmosphere full of fine particles of stone and steel.

The lecturer showed by a physical examination that the man was, without doubt, suffering with phthisis. There was no history of consumption in the family, as the father had lived to be ninety, the mother seventy, and the health of both brothers and sisters was good. And the man himself had had excellent health up to eighteen months ago. At that time he usually weighed one hundred and sixty pounds. He first had some sore throat, with a slight cough. These gradually grew worse, and in four months he was obliged to quit work. He now weighs one hundred and nineteen pounds, and expectorates constantly a large quantity of muco-purulent sputa. He had been in the hospital only a short time, and had improved some under treatment. He had had but one hemorrhage, which came about two months ago.

His chest is somewhat prominent, with depression under both clavicles. There was marked dulness below the line of the left clavicle, both anteriorly and posteriorly, attended with coarse, moist râles, chiefly expiratory, and hoarse bronchovesicular breathing. There is also dulness on the right side, from the third rib down, but less marked than that on the left, and here, too, are râles of the same character as those in the left, but more numerous and extending lower down. Vocal resonance stronger in right than in left lung, and some approach to bronchophony. Temperature in the evening 100° F. Marked clubbing of the nails, and a sluggish capillary circulation.

Prof. Da Costa, having had the sputa examined under the microscope, had found the bacillus tuberculosis present in large numbers. He called attention to the peculiar interest of this case in its bearing upon the question of the specific character of the bacillus tuberculosis, which is now attracting so much attention, and pointed out the fact that in cases of this kind, where tubercular phthisis is clearly due to the particles of stone and steel inhaled, the bacillus tuberculosis, instead of being the producing cause, is probably an after-result. This case of grinder's consumption is of especial interest as it is among the few, if not the first, in which the presence of the bacillus tuberculosis has been clearly demonstrated.

The treatment recommended was cod-liver oil, one tablespoonful three times a day, with syrup of the iodide of iron, thirty minims. For the irritating cough which was present, codeine, gr. ss three or four times in twenty-four hours, was ordered.

FRACTURE OF THE PATELLA.

Dr. Morton brought before his clinic the second case of fractured patella which he had treated with the pin lately devised by him, and which has been recently described in the *Times*.

The first case treated is now about well, showing a good result considering the amount of contusion of the parts which attended the fracture. The last patient had worn the pin only about a week, it having been put in a few days after the accident, as soon as the swelling subsided.

The lecturer believed that union of the fragments would have progressed so far in a day or two that he would be able to remove the pin and simply support the parts with a bandage until the cure should be complete. The patient was looking quite comfortable, with a prospect of an excellent result, demonstrating the value of this new device for the treatment of fracture of the patella. W. E. G.

TRANSLATIONS.

EPILEPSY DUE TO EAR-DISORDER.—Dr. Boucheron, in a contribution to the study of otopiesis, states that both in man and in animals epileptiform crises occur having their origin in some affection of the ear, or, to speak more exactly, in an excitation of the acoustic nerves.

These ear-epilepsies resemble the epilepsy, described by Brown-Séquard, which follows excitation of a sensory cutaneous nerve. In the human species, ear-epilepsy may manifest itself—

1. In infants during the evolution of the auricular affection which causes deaf-mutism. At this age the epileptiform crises are analogous to convulsive meningitiform crises.

2. In childhood, during the course of various affections of the ear accompanied by deafness, slight or profound.

3. In adult life, where ear-epilepsy (always accompanied by an affection of the ear) forms one of the varieties of late epilepsy.

Ear-epilepsy is also often observed in dogs, cats, and other domestic animals.

Auricular or ear epilepsy is characterized—

1. By epileptiform convulsions presenting all the forms occurring in pure epilepsy, with or without falling, with or without *aura*.

2. By an affection of the ear (tubo-tympanic catarrh), purulent catarrh of the tympanum, otorrhœa, impacted cerumen, lesions of the middle or internal ear, etc., with deafness more or less marked in either ear or in both ears. This is the distinctive sign of ear-epilepsy, by which it may be known from pure epilepsy.

In young children dumbness is often added to the deafness of which the epileptiform crises have been a symptom.

Ear-symptoms are often precursors of the convulsive seizures. Intelligence remains unaffected. In the cases observed by the author, the evolution of this form of epilepsy had been progressive towards cure, but with relapses corresponding with re-development of the ear-disease.

As regards their pathology, epileptiform convulsions of auricular origin have as an immediate cause an excitation, direct or reflex, of the auricular nerves,—either at their termination, along their course, at their bulbar origin, or perhaps in their inter-cerebral course,—in subjects predisposed and under certain conditions. In the same way that the epilepsy of Brown-Séquard has for its cause irritation of the trigeminal nerve, so the excitation of the sensory nerves of the ear, being transmitted to the medulla oblongata, calls into action the motor centres of this region and provokes the convulsive crises.

The source of irritation may be occlusion of the Eustachian tube, with consequent variation in the atmospheric pressure upon the membrana tympani; but a more frequent cause is impacted cerumen pressing upon the tympanic membrane. In dogs acari may be present and cause the local irritation (Nocard); but removal of the accumulation, of whatever kind, is followed by immediate cessation of the convulsions. When the source of irritation is an intracranial neoplasm, a meningitis, a necrosis of the mastoid, a hemorrhage into the labyrinth, or a suppuration or ossification of the labyrinth, auricular epilepsy may be recognized, but is not readily modified by treatment.

In conclusion, the ear may constitute, under certain circumstances, an epileptogenous zone, and the excitation of the auricular nerves may produce epileptiform crises in infancy, in childhood, and in adult life. These epilepsies of auricular origin exist also in the lower animals, such as dogs and cats.—*Revue de Thérapeutique Méd.-Chir.*, September 1.

A New Hypnotic.—Acétophênon (phényl méthyl acétone, having for its formula C_6H_5CO,CH_3), or hypnone (which is the name proposed by Dujardin-Beaumetz and Baudet), is a valuable hypnotic. According to investigations made by Papof and Neucki, this mixed acetone undergoes decomposition in the body, forming carbonic and benzoic acids, and is finally eliminated in the form of hippurates with the urine. From clinical investigations pursued by the former observers, it was found that in doses of from five to fifteen centigrammes, given with glycerin in gelatin capsules, it is well borne by the stomach, and causes a deep sleep, being thought for this purpose to be superior to chloral hydrate or paraldehyde. In doses of fifty centigrammes, when injected under the skin of guinea-pigs, it caused stupor, coma, and death in the course of five or six hours. When the remedy is continued for a number of days to patients, there is no evidence of intoleration, but the elimination of acetone by the lungs makes the breath offensive.

Hypnone is a liquid body, which, below 60° to 70° F., crystallizes in the form of white needles. It has a penetrating odor resembling both that of hydrocyanic acid and that of orange flowers. The peculiar odor makes its administration preferable in the form of gelatin capsule.

Ichthyol Plaster for Eczema.—The *Gazette des Hôpitaux* contains an article recommending the following method of treating certain inflammations of the skin. The form of a medicated pellicle, a sort of artificial epidermis, is considered more convenient to both patient and physician. The dressing comes already spread, and in the form of a plaster which needs only to be moistened with warm water in order to make it firmly adhere; it can be removed in a similar way. On the second day the dressing should be removed, and a fresh piece substituted. In cases of acute eczema (moist variety), and in all the varieties of chronic eczema, notably the eczema of the lower extremities, where the pellicle was applied in strips so as partly to overlap one another (imbricated), this treatment, aided by compression, exerted a very favorable influence; also in lichen and in prurigo good results were observed from the beginning. In some cases of psoriasis apparently good results have been obtained; but longer observation will be required to determine its real value in these cases.—*Le Progrès Médical*, No. 46.

Santonin in Amenorrhœa and in Dysmenorrhœa. — Physiological researches have shown that santonin influences the vascular system, and that it acts upon the non-striated muscle like ergot of rye and ergotin, but, unlike these, the former does not exert any injurious effect upon the stomach. The expulsion of ascarides by santonin is due to the active peristaltic movements which it causes. J. Chéron (*Revue de Thérapeutique*) claims that the action of santonin upon the vascular system, and its effects upon the muscular fibres, make it especially efficient in the treatment of those forms of amenorrhœa and dysmenorrhœa which are dependent upon adynamia, anæmia, and chlorosis, especially when the menses are as yet imperfectly established. The physiological action of santonin tends directly to remove or reduce the passive chronic congestion which determines the amenorrhœa and dysmenorrhœa in adynamic cases; and it not only relieves the utero-ovarian congestion, but acts also as a tonic to the general system. It is recommended to administer it as follows:

℞ Santonini, gr. xxx;
Glycerini, q. s.—M.
Ft. pilulæ no. 40.
S.—Take one or two pills before each meal.

Treatment of Cholera by Vesicants. —Dr. Harkin, of Belfort, in a communication to the *Revue de Thérapeutique Médico-Chirurgicale*, No. 27, declares that the disorder of the nervous system is the efficient cause of the vomiting, diarrhœa, vertigo, tremor, and muscular cramps,—the symptoms of collapse being evidently caused by an extreme irritation of the great sympathetic, while the depression of the respiratory functions and those of the circulation, through the influence of the vaso-motor nerves, constitutes the great danger of the disease. He does not find it necessary to administer remedies internally, but immediately applies an epispastic solution behind the ears and along the course of the pneumogastric nerves on the neck. From the results already obtained by this treatment the author feels warranted in recommending it for further trial by physicians living in all lands.

EDITORIAL.

THE OLDEST KNOWN ANATOMICAL PREPARATION.

THE University of Basle possesses a treasure in a skeleton prepared by no other than the founder of anatomy, Andreas Vesalius, and, as it bears the date 1543, it may be justly regarded as the oldest known anatomical preparation.

The history of this remarkable relic has recently been investigated by Professor Roth, of Basle, to whom we are indebted for a pamphlet upon the relations of Vesalius with the old Swiss town.

It is usually stated that the great anatomist paid several visits to Basle; but Dr. Roth concludes, from a careful investigation of all authorities, that his only residence was in 1543, when he came from Padua for the specific purpose of seeing his great work "*De Humani Corporis Fabrica*" through the press of Jo. Oporinus. It does not seem probable that he undertook any teaching while there; but we can well believe that students and professors were interested in the brilliant young anatomist who had even taught his great master, Sylvius, and who, scorning the prejudices of his age, had dared to study systematically the human frame, no longer relying upon cats, dogs, and donkeys. Doubtless, too, rumors had got about in the town of the great work with which the printing-presses of Oporinus were groaning, and which was destined to shatter at a blow the fetters with which for twenty centuries the doctrines of Hippocrates and Galen had bound the profession. In the sixteenth century the dissection of the human body was most reluctantly allowed by the authorities, and anatomists had to depend almost exclusively upon the lower animals for their material. Occasionally the body of a criminal was sent to the medical schools.

We can imagine the anxiety with which students and professors in Basle longed for such an opportunity to arise while Vesalius was with them. He was known to be as familiar with the parts of man as with those of a dog, and there were dark stories reported of his bold robberies of the gibbet and the graveyard. The opportunity came. On the 12th of May, Jacob Karrer was beheaded for a murderous assault upon his wife, and the body was handed over to the University to be dissected by Vesalius. As upon one occasion only, in 1531, had the dissection of a human body been allowed in Basle, we can picture the stir which such an event would create, more particularly as the demonstration was to be made by the renowned Italian professor. And, with the aid of the well-known representation, we can readily picture to ourselves the scene of the dissection, as it took place on the afternoon of the 12th of May, three centuries and a half ago. No anatomist since his time has better graced the lecture-theatre. Young and handsome, with a powerful, well-knit frame, and a strong, determined face, he was "a fluent speaker and master of an admirable style." On that day, and we may suppose for many days after, he taught to students and teachers a new anatomy, and when the dissection was completed he prepared the skeleton, and with his wonted generosity presented it to the University, where it remains to this day, in the words of the inscription, "*artis et industriæ suæ specimen.*"

No more precious gift could have been bestowed, and we find that, sixteen years later, Plater spoke of the reputation which the possession of this "anatomy" had given to his lectures. There were very few prepared skeletons in existence at the

time, and a curious instance of the estimation in which they were held is afforded by an incident in the life of Vesalius. When he went as court-physician to Madrid, Sylvius, his old master, who had relentlessly persecuted him, sent to the College of Physicians of that city and offered them a baby's skeleton if they would support him against the maligner of Galen.

The genuineness of the Basle skeleton is undoubted, as it is referred to by a succession of anatomists in the seventeenth and eighteenth centuries. Careful, indeed, should the University be of such a treasure, and proud the medical school in the possession of the only known relic of the greatest of human anatomists, the man whose daring and presumptuous spirit broke the thraldom of twenty centuries and taught men that the book of Nature was a truer guide than the books of men.

SOCIETY OF PHYSICIANS OF THE PENNSYLVANIA HOSPITAL.

ON the 17th instant will be inaugurated a new medical society, which deserves specially to be noticed. The Pennsylvania Hospital, organized in 1751, has, during the long period of its existence, not only cared for thousands of "sick and maimed and lunatics," but has also been of great service in the cause of medical education in this country. The clinical teachings given within its walls have guided medical practice in far-distant States and Territories, and, indeed, a very large proportion of the profession in the United States has walked its halls. At an early period of its existence it began its career as an educator by admitting young men, who were indentured to it for a term of years as their preceptor. Subsequent to this, as the Hospital grew and colleges sprang up, it abandoned the apprentice system and availed itself of the services of those who were already graduates in medicine, who served as resident-physicians, obstetricians,* and surgeons. At the present time, besides the physicians and assistant-physicians in charge of the male and female departments of the insane, it has an attending staff of eight surgeons and physicians, and four residents in the hospital for the sick. As many of the ex-residents and attending physicians are yet living, it has been proposed to form a society composed of the past and present medical officers of the institution, and establish an annual reunion at the old Hospital. At this meeting, to be held next week, Dr. Morton will read the annual address,† giving some curious reminiscences of the early days of the institution, and he will also exhibit some important papers which he has recently found in the archives. Short informal addresses will be made by other old residents, and the rest of the evening will be devoted to social exercises. A very pleasant reunion is anticipated.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

I MUST commence by the correction of a misstatement in my last letter. When speaking of the new Pharmacopœia, if my memory serves me aright, it was attributed to the Royal College of Physicians. This is incorrect. It is the product of the General Medical Council, a body for which no one has a good word. I dare say many of your readers do not know what this body is. It consists of representatives from the different bodies by which medical education is carried on, plus some nominees appointed by the Crown. It presides over registration; and each man, when he registers himself as a qualified practitioner, pays five pounds. Such payment is peculiarly objectionable just when a man wants every penny he can lay his hands on for other purposes, and consequently he particularly wants to see something for his money,—and what he does see is microscopically small. The Council exercises a loose supervision over medical education generally,

* The obstetrical department was closed in 1854, on account of the danger of septicæmia from the proximity of the surgical wards.

† Dr. Morton's address will appear in the next issue of the *Times*.

and looks after unworthy members of the profession when indiscreet. What the practitioner is anxious to see it do (as some practical return for the registration-fee) is to deal with the unqualified practitioner. He naturally asks, What is the good of being registered, if the unregistered are allowed to go on unchecked? It is like paying a gamekeeper and having to deal with the poacher yourself. This correction of mine is but justice to the former body, which has so little to plead for itself that the smallest injustice is a hardship for it.

We have a very extraordinary trial going on in our law courts at present which has a medical aspect. The editor of an evening daily paper wished to see a certain addition to the Criminal Acts carried through Parliament, which amendment would protect young girls against seduction by withdrawing their power of assent as regards their person until the age of sixteen is reached. Formerly a girl of twelve years could give consent, and some time ago the age was raised to thirteen. Now, juvenile depravity is so flagrant, and our streets are so crowded with child-harlots, that a number of earnest persons determined to tackle the unsavory subject. Before the close of the session society was partly amazed and partly horrified to find the business facts of brothel-keeping in all its disgusting details, especially as to the children caught for morbid lust, laid out at length in the plainest, unvarnished language. An enormous sale of the paper was the immediate result, and the prices paid for some copies were fabulous. No decent woman could pass along certain thoroughfares for the hoarse cries of jail-birds hawking this terrible literature. Thousands and thousands of copies were sold, and read by old and young alike. Children got hold of them, and became familiar with details of a most undesirable character for them, —or, indeed, for any one. It is not too much to say that a wave of psychical uncleanness has passed over the minds of the young of this generation which will leave its dirty drift on their minds for the rest of their lives; and whether the good which has resulted therefrom—viz., passing the Amendment to the Criminal Acts—will counterbalance the undoubted evil wrought remains to be seen.

One pathetic story was told of a child procured for seduction which gave a horrible shock to every reader. She was procured from her parents by fraudulent pretext, examined by a midwife, pronounced a virgin, and then left in a bedroom alone, where soon she found a strange man in the room. She screamed in terror, begging to be taken to her mother, but soon her screams were hushed. Here the relation stopped; but the preceding explanations left no shadow of doubt as to the rest.

The editor of the newspaper pledged his word for the absolute accuracy of every detail in his long list of iniquities. A commission of notables, including the Archbishop of Canterbury, sat *in camerâ* on the said details, and pronounced in their favor. The story of the poor little girl was in every one's mouth, and a mother whose child had been taken away, as she understood, to domestic service on the date given (the eve of the Derby day), began to suspect that her daughter was the child-actor in this harrowing scene. She made a stir in the matter, went to a police court, and strove to recover her child. The Salvation Army—a curious medley of fanatics, idlers, and enthusiasts—had taken an active part in the inquiry, and it turned out that one of this gang, a converted harlot and brothel-keeper, had been utilized to procure a young girl under the pretence that she needed a little girl to help her in her house-work. Further, it appeared that the child was taken away to France after the alleged outrage, and when the mother applied to one of the leaders of the Salvation Army to recover her daughter she was refused.

At last the child was restored to her mother, and with this commenced a new phase and aspect of the business. Many people felt that no motive, however excellent, could justify the abduction of a child from her home on false pretences, the subjection of her to an indecent assault, and the administration of a noxious drug (chloroform) against her will. So the public prosecutor came upon the scene and indicted the whole lot concerned,—the gentleman who planned the investigation, and who called himself "the chief director," the converted courtesan and procuress who got hold of the child, the midwife who assaulted her, and the Salvation Army gentleman who took possession of the child. They were a motley lot, and the court was crammed to hear the case, and every scrap of information as to what went on was snapped up by the newspapers and spread broadcast over the land.

A change of front was now executed, and the defence made was that the action taken was to rescue the child from a life of infamy. After taking all care to secure an untainted child, and putting forward as their original object the demonstration of how easy it was to procure a pure child for an infamous purpose, this change was rather a surprise to most persons. The defendants attacked the character of the child's mother, who, it appears, got drunk the night her daughter left her, after having been struck by her husband for letting her go. But the mother stood her own gamely, admitting her faults, but declaring her inability to see why the abduction of her child was to be justified on that account. The father's character came out unblemished. A great deal of the life of doubtful characters in a humble condition of life was laid bare in cross-examination, which gratified the prurient curiosity of many persons without any equiv-

alent good being done. To blacken the characters of the relations and friends of the child did little to vindicate the abduction; and the plea of motive, urged vehemently, did not find favor in the eyes of the legal luminaries engaged in the trial. The chief director preferred to defend himself, and of course committed much irregularity, for which the presiding judge had to check him. The procuress swore she bought the child with money down from her mother, with the latter's full cognizance of what she really was wanted for; which was quite a new turn of affairs, and in conflict with what had been sworn at first, and not at that time contradicted. Then she admitted that she had sworn lies about her past life, for which she will probably have to stand her trial for perjury when the present case is over.

The trial has created the greatest excitement, and familiarized the public mind with every minutia in connection with defloration and the life of those who live by pandering to libidinous appetites. Betwixt the first examination before the police magistrate and the trial itself, the chief director made a tour in the North of England, where he was enthusiastically received by those fanatics who disbelieve in the Vaccination Acts, who oppose, tooth and nail, the Contagious Diseases Act (Human), and who have a certain class-hatred of the patrician personages for whose perverted lust the daughters of the poor were procured by hook or crook. Here he found supporters and willing subscribers to the defence-fund. He had done a good work in exposing the social monstrosity, and "the end excused the means," they loudly asserted. During this interval such of those individuals exposed in the investigation as could leave England got away. The Minotaur has fled over sea. The two young ladies who constituted themselves a firm of procuresses "have left their country for their country's good." And it is asserted that there are a good many persons very anxious to get away before the arrival of the day of wrath. In the event of the defendants coming to grief, there is no doubt that in revenge the persons who have figured in the original investigation will be exposed. It is a case of the farther in the deeper; and we may expect some most startling disclosures to follow the conviction of the defendants.

One disclosure has been already made which has not redounded to the credit of the medical profession. For some reason or other which forensic skill has not satisfactorily cleared up, after being examined by the midwife the child was again examined by a physician,—not a poor, broken-down devil who is reduced to any makeshift to rub along, but a genuine Harley Street swell, who is closely linked with the Salvation Army,—who did not decline to accept three guineas as his fee for the examination under chloroform. This revelation decidedly gave a shock to the profession of a distinctly galvanic character, but so far no steps have been taken either to justify and defend him or to take him to task by the College of Physicians or by the leading journals. He may be congratulated on the fact that he does not stand in the dock with the defendants; for to examine a child under chloroform is surely a legal offence, in the absence of consent given by its parents and natural guardians. And there the thing stands: every one besmirched who is connected with the inquiry. One cannot touch pitch without being defiled. And how the investigation will branch out in different directions, as further legal action is taken, it is impossible to say. But the whole thing will probably be laid bare, and a huge social cancer demonstrated to exist in our midst. One seems to stand on the brink of a horrible disclosure, of which this disgusting trial is but the opening scene. Of course those persons in good social position who see disgrace and ruin staring them in the face are moving heaven and earth to close inquiry. Equally the supporters of the defendants (who regard them as martyrs) are girding up their loins for the fray. Class-jealousies are fanning the passions on both sides, and the battle will be fought out to the bitter end. No one palliates the lust which brought the whole thing about; but, then, were its magnitude and extent such as to justify these terrible disclosures, this national pollution? To steep the entire community in impurity in order to expose a certain number of persons who are a disgrace to a civilized country, is with many persons a step of doubtful desirability. However that may be, the first scene will soon close; and as to the future, we must take it when it comes.

In another recent trial a question of medical jurisprudence cropped up in the form of "disputed identity." A young lady at Brighton, a Miss Dash, was walking out with her mother, when a stranger introduced himself to her, explaining that he had met her at a ball, and giving his name as Captain Macdonald. This was a rather unusual commencement of a courtship, which, however, rapidly ripened just the same, and in a remarkably short time (to be measured by hours rather than days) the pair were married. After an equally brief honeymoon, Captain Macdonald took his final departure, leaving his recent bride disconsolate. At last her search for her errant lord resulted in the discovery that the man who took her to the altar was a married man, connected with the meat-market. She at once identified him as her husband. Troops of her friends swore positively to him, while, on the other hand, troops of his friends were equally positive that it was impossible that the said John Malcolm could have played the part of Captain Macdonald. The trial ended in the jury being unable to agree as to their

verdict, and the case had to be tried over again. In the mean time, all the facts were carefully gone over, and several who had been strong supporters of John Malcolm's innocence fell away from him, and at the second trial the gay Lothario was convicted and sentenced to penal servitude for committing bigamy.

One incident of immense real value was described, of which, however, forensic skill did not avail itself. Repeated action becomes automatic and independent of the will, and this fact has been made use of by writers of fiction. Fenimore Cooper utilizes it in "The Pirate." When "long Tom Coffin" and his marine comrade were being examined by a British officer, the latter suddenly uttered a common military command in a loud voice. Instinctively by the force of habit the marine obeyed the word of command, and so betrayed himself, while the sailor remained still and unmoved: there was no force of habit leading to unconscious betrayal operating in his case. Now, such unconscious betrayal was manifested by John Malcolm when identified by Miss Emma Dash as Captain Macdonald. When in the presence of witnesses Miss Dash saw before her the man whom she believed to be her lawful husband, and also then knowing that he was the husband of another woman, she was emotionally perturbed, as was quite natural under the peculiar circumstances of the case. What does the whilom husband do? He does not regard the lady as a stranger bringing a grave charge against him, and coolly regard her emotion unmoved himself, as he certainly would have done had she been really unknown to him. He went up to her and put his arm around her to soothe and console her. No man would do this to a perfect stranger, and in the presence of others, too. The act at once betrayed previous familiarity, to my mind. The man who puts his arm around a woman under these circumstances is no stranger, but some one who has been on terms of great familiarity some time in the past. If John Malcolm had, as Captain Macdonald, married Emma Dash, and been as a husband unto her, then his action becomes intelligible enough: it was but the repetition of an act frequently repeated in the past. Such act of unconscious betrayal has a high psychological interest attaching to it, and a value of its own,—albeit it did escape the acumen of the British bar.

J. Milner Fothergill.

BALTIMORE.

Baltimore, November 20, 1885.

ANOTHER murderer has just been acquitted in this State, in whose trial the plea of "emotional insanity" was successfully made. A man named Hance, living in the southern part of Maryland, was married in this city a year or two ago to a woman who had been an inmate of a house of ill-fame. The married life of the couple does not seem to have been a very happy one, and after a time the woman returned to her former mode of life. Hance, on his visits to the city, would visit the woman at her new abode. The testimony proved that frequent quarrels took place between the two at these visits, and one day, after one of these disagreements, Hance shot his wife through the head.

At the trial, which took place in Annapolis, Senator Voorhees was one of the counsel for the defence. The killing was admitted, but, from the testimony of the neighbors and kinsmen of the accused, a case of emotional insanity was made out by the learned counsel. It is questionable, however, whether this would have had any weight with the jury had not the eloquent arguments of the attorneys and the family influence of the accused (which is very great) profoundly impressed the twelve good men and true. At all events, the prisoner was acquitted, "amidst tremendous applause," as the papers stated. It is significant, however, that the finding was simply "not guilty,"—in other words, an absolute acquittal,—and no reference was made in the verdict to insanity. This specious plea was simply introduced as a cover to secure an acquittal without making the whole trial a travesty of justice. There was no evidence whatever that the accused had, either before or after the murder, given any indication of mental disease, except the fact of his having married a prostitute whose charms had fascinated him. It is a satisfaction to know, however, that the verdict of the jury cannot be quoted as a precedent in future cases of this sort, since it completely ignored not only the facts presented by the commonwealth, but also the plea of the defence.

The new hospital for the Marine Hospital Service is nearing completion, and will be ready for use during next year. The wards are one-story pavilions. There are separate buildings for the administration, kitchen, surgeon's residence, etc. The hospital is beautifully located about half a mile north of the city, and commands a fine view of Druid Hill Park.

PROCEEDINGS OF SOCIETIES.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, November 5, 1885.

The President, B. F. Baer, M.D., in the chair.

(Continued from page 178.)

OÖPHORECTOMY FOR OVARALGIA.

DR. WILLIAM GOODELL exhibited the ovaries from two cases of oöphorectomy, with the following histories.

When the patient, an unmarried woman,

aged 30, first consulted him, she weighed two hundred and thirty-six pounds; but at the same time she was very weak and could barely walk. She suffered excessive pain at her catamenial periods, which appeared only at long intervals. She had cataleptic and hystero-epileptic fits, and complained of very constant and acute ovarian pains. Her urine was passed but once a day, and this act was attended with much suffering. The womb was enlarged and the ovaries were very tender indeed; but nothing else abnormal was discovered. Asafetida and the bromides were prescribed in large doses, and she was advised to try the rest treatment. Fourteen months later she was again brought by her physician to consult Dr. Goodell. She now weighed only one hundred and twenty pounds, having lost one hundred and sixteen pounds, and she was in every respect worse, her ovarian pains being now constant and very acute, requiring large doses of morphine to control them. Her catamenia had not appeared for nigh four months, and tonics seemed to have no effect whatever on her. Her physician was compelled to be in constant attendance on her, and was liable to be summoned at any hour of the day or night to give her a hypodermic injection. Masturbation was suspected, but she always denied practising this habit.

Nothing further could be done than the operation of oöphorectomy, which was accordingly performed a few days later at the hospital of the University. The ovaries were found much enlarged from cystic and interstitial degeneration, but there were no evidences of peritonitis or of cellulitis, which had been suspected. A corpus luteum existed in one ovary, a rectal hemorrhage or vicarious menstruation having taken place a few days before the operation. Her ovarian pains at once left her. She needed but very few doses of opium, which were given by rectal suppositories. Her convalescence was prompt, and she returned home in less than four weeks, free from all pain and in a fair way to get perfectly well. The case was a typical one of the advantages of oöphorectomy; yet he (Dr. G.) thought that the operation is now performed altogether too frequently.

OÖPHORECTOMY FOR BLEEDING FIBROID OF THE WOMB.

In this case the lady was 37 years of age, and had been married eleven years. She gave birth to a child about seven years ago, and since then had had one premature birth at seven months and one miscarriage. She first noticed an abdominal tumor nine years ago, but her catamenia began to be free some time before this. Late in the year 1881 the catamenia began to be excessive. As nothing served to check them, early in the following year Dr. Goodell was consulted. He found multiple fibroids of the womb. Six tumors could be readily made out, of which two seemed pedunculated. The sound gave a measurement of four and a half inches. Under ergot and ammonium chloride the patient improved for several months; then the menorrhagia became worse, and finally a dribbling of blood kept up between the periods. In May of the present year she again consulted Dr. Goodell. She had been dribbling continuously from January, and was much reduced in strength. Being a brunette, she exhibited the facies uterina in a most marked degree, the pigmentation being very dark and extensive. The womb now measured seven and a half inches.

She was admitted into Dr. Goodell's private hospital, and on May 24 both ovaries were without difficulty removed. They were greatly enlarged by follicular degeneration, a condition which Dr. G. had repeatedly seen in cases of fibroid tumor. The effect of the operation on the tumors, and especially on the main one, was astonishing. After two weeks this fibroid had diminished in length nearly a hand's breadth. Her recovery was prompt, and she was sent to Atlantic City to recruit.

On July 10, just forty-seven days after the operation, she called on Dr. Goodell, who found the tumors very greatly reduced in size and the uterine cavity measuring only three and a quarter inches, a diminution of four and a quarter inches. This extraordinary amount of diminution, in spite of the fact that the obliteration of the ovarian blood-vessels cut off only a small portion of the blood-supply to the womb, drove him to the conclusion that the ovaries were the important factors in inviting the blood to the womb. Every successful case in which he had removed the ovaries for fibroid tumor of the womb had been followed by the menopause and by rapid diminution in the size of the tumor. But in his hands and in those of others this operation is more fatal than that of ovariotomy. During the ten months of the present year he had had twenty-five cases of ovariotomy, with but one death, and that one in a lady operated on at her home, two hundred miles from Philadelphia. For simple cases of oöphorectomy the mortality should not be greater than that of ovariotomy. But when complicated with the presence of a large or an adherent fibroid tumor, the operation is often one of great difficulty. Twice during the past year he was unable to reach the ovaries and was compelled to abandon the operation, because in neither case was the woman willing to undergo the risk of having hysterectomy performed. Each case recovered, and while the women were under observation the tumors appreciably lessened in size, as if the shock of the exploratory incision had temporarily suspended the ovarian influence.

Dr. MONTGOMERY was glad to hear the

good results in Dr. Goodell's cases. In a few of the cases upon which he had operated the menopause did not at once occur, sometimes not for two years after the operation. In such cases the tumor did not decrease in size while menstruation continued. In the case of hysterectomy for fibroid tumors reported by Dr. Montgomery at the last meeting, the temperature at no time exceeded 101⅗°, and the patient left the hospital to-day perfectly well. He preferred removal of the uterus and its appendages entire when the ovaries cannot be removed in consequence of previous inflammatory changes. Ligation of blood-vessels supplying the tumor might be useful when nothing better could be done.

Dr. Baer thinks that when the ovaries can be removed, it is the preferable operation.

Dr. Goodell has been so uniformly successful in removing the ovaries for the cure of fibroid uterine tumors that it is his choice. He has been notified that in a case of fibroid tumor of the womb in a woman aged 33 years he will be called in consultation: this will be the third. He will advise removal of the ovaries; if at the time of operation that is not found possible, he will close the incision, as the other operation is very dangerous and the patient can certainly live a few years as she is. In only one case of his oöphorectomies had the menses continued, and he thinks that in that case there must have been some supplementary ovarian tissue.

OVARIOTOMY.

Dr. Montgomery exhibited for Dr. Warder a large ovarian tumor and related the following history. The patient was a young woman. Her menses commenced at seventeen years of age, and had always been irregular. They ceased entirely for twelve months, and at the same time the abdomen was enlarging until the tumor reached above the navel. Fluctuation was doubtful; the mass seemed quite solid and pressed the uterus down into the pelvis. Anæsthesia did not relax the abdominal wall, and diagnosis was doubtful. An exploratory incision showing the pearly tint of an ovarian tumor made it sure. Nothing would pass through the trocar, but some of the jelly-like contents of the tumor escaped beside it and passed into the abdomen. The large cyst was filled with small cysts. The patient did well for one week; then the pulse became rapid; but she has since been doing well, and is now rapidly recovering.

Dr. Goodell thought that the danger from the escape into the abdomen of cyst-contents is overrated.

Dr. Baer said that in the early stage of ovarian tumors metrorrhagia is sometimes present; sometimes the menses are entirely absent. He should like to hear from the Society some reason for this inexplicable difference.

Dr. Goodell had observed the same facts, but could throw no light upon the subject.

Dr. Montgomery remarked that in this case both ovaries had undergone cystic degeneration. The second ovary contained numerous small cysts.

Dr. Baer inquired about the treatment of the second ovary.

Dr. Montgomery replied that it was removed.

SOME USES OF COCAINE IN GYNÆCOLOGY.

BY CHARLES HERMON THOMAS, M.D.

Seldom does a new drug reach so sure a place in the confidence of the medical profession as that accorded to cocaine. I early began its employment in ophthalmic practice, and soon extended its use among other things to a variety of gynæcological applications. The results obtained have been so satisfactory that I now never go to such a case without cocaine in my bag or pocket. After considerable experience in its use, I am convinced that it is quite as valuable in the latter class as in the conditions for which it was originally recommended. That it is a local anæsthetic, when applied to mucous surfaces especially, is a familiar fact; but its property of rapidly reducing engorgement and swelling of the same class of tissues is not so generally recognized, notwithstanding this is a point of considerable practical importance. This action of the drug is readily verified by observing the marked paleness and shrinkage which follow in a few moments after its application to surfaces thus affected. While this condensation of tissue is to a considerable degree temporary, it seems to be of longer duration than the accompanying anæsthesia. In some cases the good results obtained by reducing hyperæmia in this manner appear to be permanent. The common fear that it will fail to prevent pain may usually be overcome by placing a few drops of the solution on the tip of the patient's tongue, when the numbness produced is quite sure to induce full confidence in its efficacy. Cocaine hydrochlorate is the salt upon which my experience is based.* A four-per-cent. solution (gr. iiss to ƒ3j) in water acts well for most purposes, though a somewhat weaker or stronger one may sometimes be substituted with advantage. The addition of boric acid in the proportion of gr. ij to the ƒ3j insures stability of the solution, while a little glycerin prevents too rapid drying.

When used, it should be applied with thoroughness, the parts being first freed from mucus, and some minutes allowed to elapse for its effects to develop; the time should be *not less than two minutes*, and, in cases where considerable pain is to be anticipated, a strong solution (ten per cent. or more) may be employed, and the application repeatedly made at intervals of two minutes, when in five or

* The price has been reduced to ten cents a grain or less.

at most ten minutes from the beginning the full effects of the drug may be looked for. That the anæsthesia produced by cocaine is profound I have personally experienced, having made use of a four-per-cent. solution by injection into the nostrils previous to an application at the hands of Dr. Harrison Allen of the galvano-cautery to the nasal cavity. The cautery had been applied on a previous occasion without the full effect of cocaine being produced, and the pain was severe. With it not the slightest pain was felt, and I was conscious of the action of the cautery only by the hissing sound produced.

I have found it particularly valuable in certain cases of cervical endometritis, in which, though there may be no erosion externally, and but little characteristic discharge, there is a state of extreme hyperæsthesia existing about the region of the internal os uteri,—a probe or cotton easily bringing blood, and any application made to the part is liable to produce bleeding and severe radiating and ovarian pain. Cocaine carefully applied with the syringe or the cotton-carrier prevents the pain and bleeding which would otherwise follow the necessary medicinal application. The swelling is also materially reduced, and the congestive or inflammatory stenosis which usually exists is consequently for the time relieved, so that applications to the part itself, as well as to the entire endometrium, are greatly facilitated. In urethral caruncle sensibility may be so destroyed by cocaine that the painful excrescences can be clipped off and the site painlessly cauterized. Cocaine is also extremely useful in painful irritation and inflammation of the female urethral tract, and especially of the part just within the meatus, a condition attended with distress frequently referred to the bladder. Appropriate medication is painlessly made after its application, which may be conveniently done by means of the glass medicine-dropper. As a means of preparation for the operation of stretching either the urethra or the cervix uteri it is of unquestionable value. To precede the application of caustic to chancre it is also effective. I am informed by my friend Dr. Levis, who has had a large surgical experience with the drug, that in plastic operations upon the vagina, where considerable surfaces are to be flayed, the cocaine-anæsthesia is insufficient to prevent pain. It has been recommended in dysmenorrhœa, and there is good reason to believe from several reports which have been made that it is capable of producing excellent results when applied to the os uteri and to the cervical cavity by means of a small cotton tampon. I tested it recently in a case of uterine colic, using it hypodermically in two doses of one grain each about half an hour apart, but without appreciable relief. Some general nervousness was complained of, but otherwise there were no uncomfortable results. It has been tried internally in doses of one grain or more in the vomiting of pregnancy, and has met with some favor, but in the only case within my own knowledge it entirely failed.

In a case of painful vaginismus, with dyspareunia, brought me by a practitioner from a neighboring city, the condition was quickly relieved by the local application of cocaine, and a complete examination was easily made, where without its use general anæsthesia would have been necessary. In a case of hyperæsthesia of the vagina with mild vaginismus, in which frequent local treatment was required, a suppository containing one grain of cocaine introduced into the vagina a half-hour before each treatment entirely abolished the spasm, and rendered the introduction of the speculum easy and comparatively painless. Cocaine suppositories also produced excellent results in a case of rectal tenesmus in which opium had proved inefficient.

Cocaine has been recommended in operations for lacerated cervix and in lithotrity. I have not made use of it in either of these applications, but strongly believe in its value.

In one hyperæsthetic patient in whom violent pain was developed on slight provocation, and who required local treatment of the cervix uteri and urethra, but who suffered so much from ordinary applications that the local benefit was fully counterbalanced by harm done nervously, it became necessary to suspend treatment on this account. After cessation for six months, treatment was resumed under cocaine, and it has since been in every way satisfactory, the pain formerly produced by applications to the cervix being entirely absent. In the same patient painful irritability, with spasm of the bladder simulating cystitis, which was not entirely relieved by the opium suppository and other measures, yielded completely and thus far permanently to a single injection of one grain of cocaine thrown into the bladder. The resumption of treatment in this instance was largely due to the enthusiastic approval of the husband, who had himself experienced complete relief from the injection of a drachm of the two-per-cent. solution into the deep urethra for a violent urethrismus. In another instance, a woman with irritable piles, who was suffering extreme discomfort, the piles shrank and turned pale under the cocaine application, and were then painted with tincture of iodine with entire absence of pain at the time, and with much subsequent benefit.

Dr. KEATING had used cocaine for some time in the same class of cases. He now uses eight-per-cent. solutions with great success, especially in children's throats. He employs salicylate of cocaine in diphtheria in a five- or six-per-cent. solution. Sensibility disappears in a short time, and he can then use any application without discomfort. He applies carbolic acid, tincture of iodine, etc., in this manner without exciting pain. He also applies cocaine before injecting carbolic

acid into piles, and also applies it on cotton to prevent its action ceasing too soon.

Dr. THOMAS said that the strength of the solution may, with propriety, be greatly varied, and that in his practice in ophthalmic cases a one-per-cent. solution had been found strong enough to be of considerable value in conditions of irritation such as that produced by foreign bodies in the eye; but in other cases, as urethral caruncle, it might be well to use it even in saturated solution. The question of strength is largely a question of expense, for in local application made under the observation of the physician no toxic results are likely to be produced.

W. H. H. GITHENS, M.D.,
Secretary.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

MEETING OF NOVEMBER 12, 1885.

The President, J. C. WILSON, M.D., in the chair.

DR. FUSSELL presented specimens from a case of

MASTOID DISEASE.

Male, æt. 25 years. Never had scarlet fever. Since vaccination at the age of five years had had occasional attacks of suppuration of the middle ear. General health was good. Was first seen by Dr. Fussell July 14. For several weeks he had had earache, with one slight chill. When seen, hearing was very poor, tympanic membranes opaque, swelling and redness of the left mastoid process, and temperature elevated. His general condition grew worse, and an incision was made over the mastoid process, but it failed to find pus. On extending this incision a few days afterwards, pus flowed freely, and he was much relieved. He afterwards grew worse, fell into a typhoid condition, and died July 24. Before death, blood oozed freely from the cutaneous surface. At the autopsy the mastoid cells were found filled with pus. In the inner half of the process was a large, irregular cavity filled with a pultaceous mass of necrosed bone: this communicated with the middle ear. The walls of the lateral sinus were thickened, easily detached from the bone, and the seat of a purulent inflammation. The sinus contained no thrombus. The meninges over this part were discolored, though not inflamed; but there was a patch of inflammation over the anterior edge of the left lobe of the cerebellum. Brain-substance was normal. Remaining organs were not remarkable, except the right lung, which contained in its apex two small abscesses. From the condition of the sinus, the reporter thought there had been an actual admixture of pus with the blood.

Dr. PACKARD presented an

ANOMALOUS LUNG.

It was taken from the body of a negro who died of Bright's disease. From the inferior surface of the lower lobe of the right lung springs a tongue-shaped process of pigmented, crepitant lung-tissue, two and a half inches long and two inches wide at the base, resting upon the diaphragm, its upper surface being in apposition with the under surface of the lower lobe. Dr. Packard had recently seen in the body of another negro a similar anomaly, except that the process was smaller and situated more anteriorly.

Dr. MUSSER presented a

CYSTIC KIDNEY.

It was the right kidney, and was taken from the body of a man, æt. 72 years, who died of apoplexy. The kidney was cirrhotic and contained two cysts, the larger occupying the upper one-fourth of the organ. Its walls were firm, and it contained clear fluid, in which floated cheesy masses, which the reporter thought were degenerated pus. When first seen, the patient was passing small quantities of bloody, highly albuminous urine, and complained of pain in the right renal region. These symptoms were apparently due to an acute process grafted upon the chronic lesion. The blood and most of the albumen disappeared, but the pain persisted. Was this pain due to the cyst?

Also, a

CARCINOMA MAMMÆ,

removed from the body of a woman æt. 75 years. The breast had been injured eight years ago, and three years afterwards the tumor was noticed. There was never any pain in the tumor. The lymphatic glands of the axilla were involved. In addition, there was a large lipoma of the back of the arm. She had frequent attacks of pain in the tibiæ and left parietal bone, apparently due to periostitis, and not to any secondary growth. There was no syphilitic history.

Also, specimens from a case of

DIABETES MELLITUS.

Female, æt. 43 years; had a vesico-vaginal fistula fourteen years. Diabetes had existed without apparent cause two months. Patient was unusually fat, and had lost no weight. She died of coma. Temperature in the abdominal cavity three hours after death was 107.8° F. Liver large and fatty; gall-bladder contained thirty stones; kidneys fatty; pancreas normal. Blood had a most marked lactescent appearance, and after standing twelve hours globules of fat collected on its surface. Lacteals in the mesentery engorged with chyle. Microscopic examination of lungs showed no fat-emboli. In the urinary bladder was a large phosphatic calculus.

Dr. OSLER thought the peculiar condition of the blood was what we should find nor-

mally in a person dying during digestion, and called attention to the fact that very frequently in diabetics there is engorgement of the lacteals.

Also, a

FŒTUS PAPYRACEUS.

The mother was delivered in the morning of a mature, living child, and in the evening of this fœtus. It is apparently of the fifth month of pregnancy, and, with the exception of shrivelling and paling of the skin, is quite normal. The cord is thin and soft, its length unknown. The placenta is thin, flat, compact, and whitish yellow, apparently having undergone complete fatty degeneration.

Dr. J. B. ROBERTS presented a small tumor, the size of a hickory-nut, which he had removed from the back of the wrist of a young man. It had the clinical appearance of an ordinary ganglion, but attempted evacuation showed it to be solid. It was then enucleated and found to have been developed within the theca of the tendon going to the middle finger, and probably between its fibres. The great rarity of solid tumors in this locality was mentioned.

Dr. OSLER asked if the patient had a rheumatic history, although this specimen was rather large for a subcutaneous nodule occurring in rheumatism.

Dr. ROBERTS knew nothing of the history.

Dr. NANCREDE presented fluid from an encysted hydrocele. The fluid contained large numbers of dead spermatozoids.

Dr. HUGHES presented a

PRIMARY CARCINOMA OF THE LIVER.

Female, æt. 58 years. A daughter died of cancer of the uterus. She had been in good health till eighteen months ago, when flesh and strength began to fail. With this there were occasional attacks, lasting about a week, of headache and sick stomach, followed by diarrhœa. There was pretty constant lancinating pain in the hepatic region. Five months ago she had an attack of jaundice (her only attack) lasting two weeks, and at this time a tumor was detected in the liver. At the autopsy the liver was found much enlarged, and scattered through its substance were firm cancerous nodules, varying in size from an orange to a pin-head. In addition to these there were several cysts, one in the left lobe two inches in diameter, filled with clear fluid. The liver-substance between the cancerous nodules was normal. The gall-bladder was full of healthy bile, and the ducts patulous. There were no enlarged glands in the fissure of the liver, but the retro-peritoneal and mediastinal glands were increased somewhat in size and the seats of secondary deposits. With these exceptions, there was no growth outside the liver. The intestines were crowded into the left side of the abdomen by the enlarged liver. The stomach was very small, only one inch in diameter at its fundus. There was an intussusception three inches in length at the ileo-cæcal valve, which, on being reduced (which was effected with some difficulty), showed the apposed surfaces of peritoneum covered with lymph.

Dr. FORMAD presented specimens and read a paper on

AN ANALYSIS OF TWO HUNDRED AND FIFTY AUTOPSIES ON DRUNKARDS, ILLUSTRATING THE MOST PROMINENT ANATOMICAL LESIONS OF CHRONIC ALCOHOLISM.

He considered the most conspicuous lesions to be cyanotic induration of the kidneys, fatty infiltration of the liver, and mammillated stomach. His cases had been those in which there had been a history of a long-continued series of debauches, the subjects often dying in one of these debauches, and did not include moderate drinkers or those who perished after imbibition of an enormous quantity of alcohol without any previous chronic excesses. He thought that the exposure, irregularities of diet, etc., incident to a state of drunkenness had much—probably more than the alcohol itself—to do with the production of the lesions; but it was not at all possible to separate one from the other. He gave a long list of lesions considered by various authors to be results of chronic alcoholism, among which the cirrhotic liver with contraction held a prominent place. He had himself at one time considered cirrhosis a very frequent, if not almost necessary, concomitant of long-continued, excessive use of alcohol, and had even testified in court that a certain person was not likely to have been a hard drinker, because at the autopsy no cirrhosis of the liver was found. He had thought, too, that the connection between the two was so close that it was impossible to have a case of cirrhosis without a previous history of alcoholism, as is held by various authors. Therefore it was surprising to him to meet in his two hundred and fifty autopsies with only six cases of cirrhosis of the liver with contraction. In two hundred and twenty cases the liver was considerably or even very much enlarged, the enlargement in most cases proving to be due to a fatty infiltration. Cyanotic induration of the kidney and chronic gastritis, with mammillation of the stomach, were found in nearly every case. This cyanotic induration is peculiar, and differs from the cyanotic induration due to heart-disease. At a future meeting he will give a detailed account of the above lesions and a more extensive analysis of the cases.

Dr. TYSON could not speak from a systematic observation of a large number of autopsies in the cases of confirmed drinkers, but he remembered distinctly being surprised in several cases by the absence of cirrhosis where he confidently expected to find it.

Dr. WILSON said that Anstie, in the article

*

on alcoholism in Reynolds's "System of Medicine," had called attention to the comparative infrequency of contracted liver in confirmed drinkers. This observer, in an extensive out-patient practice in London, had seen large numbers of cases of alcoholism, but very few among them presented the physical signs of cirrhotic (contracted) liver. The experience of the staff at Blockley Hospital sustains this view. There many of the patients are soaked with alcohol; but even among those whose death is directly or indirectly due to alcoholic excess, fatty liver is much more common than contracted liver.

Dr. OSLER thought the experience of pathologists and morbid anatomists with histories of patients is not of the most satisfactory character, he often having had cases to dissect where he knew very little of the history. Before saying these cases were chronic alcoholics, Dr. Formad should present more specific statements about them. His own experience with livers in a large number of autopsies on cases of chronic alcoholism had led him to divide them into four classes: 1. Those in which the condition of the liver is pretty satisfactory: some of these cases may take alcohol for many years and yet the liver pass muster. 2. Fatty cirrhotic livers; the cirrhosis may not, perhaps, be distinct to the naked eye, but plainly shown by the microscope: this is the largest class. 3. Hob-nail livers: these he would say were much more common than in Dr. Formad's series. 4. Hypertrophic cirrhotic livers. The difference between his observations and those of Dr. Formad might possibly be accounted for by a difference in the form of alcoholic beverage taken. He had not observed the special form of kidney described by Dr. Formad. In reply to a question, he said, in order of frequency, he would place them: fatty cirrhotic, hob-nail, hypertrophic cirrhotic, apparently normal.

Dr. S. SOLIS COHEN said there were certain theoretical considerations which suggested themselves in this connection. The text-books teach that the lesions of alcohol are of two kinds, sclerosis and steatosis. It is known that in some organs the fibrous change precedes the fatty one. The latter is the higher grade of degeneration. The subjects of Dr. Formad's autopsies were confirmed whiskey-soakers, in whom one would expect to find more intensity of degeneration than in those whose use of alcohol, though persistent and excessive, was not so outrageous. Another point, which had not been alluded to, was the fact that some lesions might result from a local action of the poison upon the tissues, while others might be due to its systemic action. No study of the subject could be complete in which these points were overlooked.

Dr. RANDALL suggested that the point touched upon by Dr. Osler—the character of alcoholic beverage—might be very important. In Vienna, among beer-drinkers, he had found the fatty liver much more common than the cirrhotic; while in England, where much gin is drunk, and he should suppose in Scandinavian countries, where they drink altogether strong spirits, the cirrhotic liver is doubtless comparatively frequent.

Dr. MUSSER had recently had to go over the records of the Pathological Society, especially in liver-diseases, and had found the total experience of different observers the same as Dr. Formad's, and also in those cases cirrhosis was caused not so much by heavy drinking as by persistent drinking of spirits on an empty stomach.

Dr. FORMAD presented the

SAC OF AN EXTRA-UTERINE PREGNANCY.

The woman from whom this was removed had not suspected that she was pregnant. She was in perfect health till twelve hours before death, when she was suddenly seized with excruciating pain in the left groin, rapidly followed by collapse. On opening the abdomen, it was found to contain at least a gallon of partly-clotted blood. About the middle of the left Fallopian tube was the sac, with a rent in its posterior wall. This sac was one inch in diameter, and contained clotted blood and placental tissue. The uterus was twice its normal size. The fœtus was not found.

Also, an

ANEURISM OF THE ASCENDING AORTA, RUPTURING INTO THE PERICARDIUM.

The patient was a laboring-man, and had considered himself in perfect health. He died very suddenly. The aneurism, one-half inch in diameter, was situated just above the posterior aortic leaflet, and had broken through the wall of the aorta at the point where it touches the descending cava. The cavity of the pericardium was fully distended with clotted blood.

W. E. HUGHES, M.D.,
Recorder.

THE NEW YORK STATE MEDICAL ASSOCIATION.

A MEETING of the Association was held in New York November 17, 18, 19, and 20, 1885.

The President, Dr. John P. Gray, of Utica, occupied the chair at most of the sessions. The total number registered amounted to about two hundred and twenty; the total membership throughout the State is about five hundred and fifteen. The attendance at the different sessions was usually good. The President for the next year is Dr. E. M. Moore, of Rochester.

Dr. Gray, in his address on "The Relations of the State to Medical Science," pointed out

those relations as they exist in New York State at the present time, and, remarking upon proposed changes, he expressed his views in opposition to a State Board of Medical Examiners or of separating the power to grant diplomas and license to practise from the medical teaching bodies. Our medical colleges had had a great deal to contend with in their efforts to elevate medical education, but their efforts had to a considerable degree been crowned with success; and they would probably succeed, as the need of it became more and more apparent, in raising the standard of preliminary medical education.

The reports of the Presidents of the several Branch Associations and of the New York County Medical Association showed that there had been a good deal of scientific work done throughout the State during the year.

Dr. Alfred L. Carroll, in an address on "State Medicine," pointed out the need of more thorough instruction in sanitation (as the term was used in its restricted sense) than at present generally existed among physicians. The greatest ignorance of sanitary matters, and also of orthography, was shown to exist among a large number of applicants for positions on local boards of health. The requirements in England of one about to enter upon the study of medicine and of those about to go out into active practice might seem to be pretty severe and extensive, but they were no more than should be exacted of every man who had the health of his fellow-beings placed in his care. The trouble with the colleges here was not that they failed to give opportunity for a good medical education, but that they did not compel every student to avail himself of that opportunity to the greatest extent.

Dr. Didama, in a paper on "Tubercular Consumption; is it ever Inherited?" expressed his belief in the germ-theory of the disease, and said he did not think it was ever inherited. It had never been found to exist in the body of a fœtus, and the statistics of life-insurance companies showed the great numbers of those suffering from the affection whose parents had been free from tuberculosis. He believed that the families of those having tubercular consumption were more likely to acquire it than others, because of exposure to infection and an inherited feeble constitution.

Dr. Rochester, in discussing the paper, related two cases which were opposed to the view that the disease was not hereditary. A child died three weeks old with the symptoms of consumption, and at the autopsy one lung was full of miliary tubercles and the other contained a cavity the size of a hickory-nut. The father had died of consumption prior to the birth of the child; the mother was a healthy woman. In a second case the child suffered from all the symptoms of consumption for some time, and died aged eighteen months. The father had died with consumption before the birth of the child; the mother was healthy.

Dr. Simeon Tucker Clark read an instructive paper on "Psoitis and Peripsoitis; their Pathology and Differential Diagnosis." The paucity of the literature on this subject was shown. The author narrated three cases which had come under his observation, in which psoitis had followed an injury,—in one of the cases the injury having occurred during roller-skating, and in another while throwing grain-bags upon a wagon. The patient felt pain in the region of the psoas muscle, extending down the leg, the motion of the limb being painful. A boggy tumor then appeared in the hypogastrium. This tumor was at first composed of serous exudates, which if allowed to remain would undergo pustular change, invade the neighboring tissues, the periosteum, and bone. The object of the treatment was to prevent this train of symptoms. The tumor on being recognized should be emptied of its contents, the wound being treated antiseptically in the usual manner. In one of the cases reported the patient died, and the extension of the disease from the soft parts (where it had evidently started) to the periosteum and bone was demonstrated. In another case the discharge took place spontaneously into the bladder, but later an external opening was made and the patient made a good recovery.

Dr. Frederick Hyde, in discussing this paper, considered it as one of very great importance, for many of these cases doubtless went on unrecognized, and led to a condition of things called Pott's disease, etc. He had seen some cases of the kind described by the author, and the treatment which had been suggested was of the utmost importance to prevent the decomposition of the pus, the destruction of the periosteum and bone, and the development of sepsis.

The short communications on the subject of "Shock, and the Effects of Injuries on the Nervous System," by Drs. Charles W. Brown, Frank H. Hamilton, and E. S. F. Arnold, brought out some interesting points, more particularly perhaps regarding insidious shock as seen by Dr. Brown, and Dr. Hamilton's opinion concerning railroad shock, and Dr. Arnold's concerning the part played by the sympathetic system in the production of shock. Dr. Hamilton said that if there was a peculiar form of shock which deserved the name of railroad shock, it was that in which the peculiar motions (like cracking a whip) during an accident while sitting in a railroad-car caused a strain or injury to the spinal ligaments and parts which sustained the vertebral column rather than to the spinal cord itself, the immediate symptoms not being of a grave character, but assuming a type which indicated secondary implication of the spinal cord. Dr. Arnold thought the symptoms in shock indicated a cessation of nutrition of

vital organs, which in health was controlled by the sympathetic system. It was analogous in character, but less in degree, to the condition produced by lightning and hydrocyanic acid. It was true, some claimed that death from hydrocyanic acid was due to cessation of heart-action, but this might be due to the action of the drug upon the sympathetic system, destroying its life, and with it the vitality of all the organs over which it presided.

Dr. Carlos F. McDonald reported an interesting case of "Gunshot-Injury of the Head followed by Insanity, Cerebral Cyst, Operation, Recovery." The injury was situated over the right first frontal gyrus, corresponding to the junction of the anterior and middle thirds, three-eighths of an inch to the right of the median line. A physician had extracted the pistol-ball, and the opening in the skull became covered with fibrous material. The patient manifested symptoms of insanity for some time after the accident, and the brain beneath the wound was penetrated by the hypodermic needle in four places, the last time nearly clear serum being found and about two drachms removed. When the patient came from under the influence of the ether he expressed great pleasure at relief from pain, which he had long suffered over the wound. He was rational, and gave a complete history of his case, except for a period when unconscious. None of his old symptoms had returned. The great rarity of cerebral cyst was mentioned.

Dr. Ely Van de Warker read a paper on "The Medico-Legal Bearing of Pelvic Injuries in Women," in which it appeared that suits based on supposed injuries to the pelvic organs in women from falls, etc., sustained from bad sidewalks, railroad injuries, and the like, were becoming quite numerous, and they were almost invariably without foundation; yet the difficulty of obtaining a thorough examination of the patient, to show that her symptoms depended upon prior conditions independent of the accident, and the fact that the defendant in the suit was usually a supposed wealthy corporation, without feeling, led the jury very unjustly to render a verdict in favor of the complainant.

The following is a leaf taken from the programme, and constituted the work of the night session of the 17th of November, the discussion being completed the next morning:

"DISCUSSION ON PNEUMONIA.

"This discussion was opened by Austin Flint, M.D., with a paper in which he propounds eight questions relative to the nature, pathology, prognosis, and treatment of acute lobar pneumonia.

"QUESTION 1. Is acute lobar pneumonia a primary local inflammatory disease, or is it an essential fever, the pulmonary affection being secondary thereto and constituting its anatomical characteristic?

"QUESTION 2. What facts and rational grounds, with our present knowledge, can be cited in support of the doctrine that acute lobar pneumonia depends on the presence of a specific micro-organism?

"QUESTION 3. What conditions or circumstances incident to acute lobar pneumonia tend to render the disease fatal?

"QUESTION 4. Are there known remedies or therapeutic measures capable of arresting this disease, or of exerting a curative influence by either shortening its duration or conducing in any way to a favorable termination?

"QUESTION 5. Is blood-letting ever indicated in this disease, and, if so, what are the circumstances indicating and contra-indicating this measure of treatment?

"QUESTION 6. Is alcohol useful in the treatment of cases of acute lobar pneumonia, and, if so, what are the indications for its use, and how is its use to be regulated as regards the quantity given, etc.?

"QUESTION 7. To what extent is it safe and useful to employ antipyretic measures of treatment in cases of acute lobar pneumonia, inclusive of the cold bath, sponging the body, or the wet sheet?

"QUESTION 8. Do relapses of acute lobar pneumonia ever occur during or shortly after convalescence, and does this disease involve any special liability to other diseases or sequels?"

While Dr. Flint's views on the subjects for discussion were already pretty well known to the profession, the matter contained in his paper was well arranged and clearly stated, and the contribution will constitute one of the ornaments of the forthcoming volume of Transactions. The author gave his reasons for believing that acute lobar pneumonia is an essential fever. He also believes the disease is due to a specific micro-organism. The value of some remedies was pointed out, more especially of quinine, of alcohol, of blood-letting, and of the wet sheet,—all under suitable circumstances or circumstances indicating their use, for it was to be remembered that acute lobar pneumonia tended naturally to recovery. Dr. Flint never knew a relapse to occur in acute lobar pneumonia during or shortly after convalescence.

In most respects, the gentlemen who discussed the questions expressed views in harmony with those of Dr. Flint.

Dr. Austin Flint, Jr., read an address on "Some of the Relations of Physiology to the Practice of Medicine," and Dr. E. G. Janeway, one on "Pathology." They were interesting reminders of the past and present advancements in medicine, and of the interdependence of the several branches of medicine.

Among other interesting papers was one by Dr. Isaac E. Taylor on "Recto-Labial or Vulvar Fistulæ," in which he advocated treatment

by ligature; one by Dr. Frederick Hyde on "The Difference in the Symptoms of Strangulated Oblique Inguinal Hernia;" "Recurring Luxations," by Dr. E. M. Moore; "A Case of Gall-Stones, Patent and Concealed; Exploratory Laparotomy, with Autopsy Ten Weeks Later," by Dr. W. W. Seymour; "The Action of Micro-Organisms upon Surgical Wounds," by Dr. F. S. Dennis; "Causes of Failure in the Treatment of Urethral Stricture by Electrolysis," by Dr. Robert Newman.

Altogether there were fifty-three papers for presentation before the Society. Many of them were not read, and a few of those which were read had the fault of trying to be complete treatises on the subjects with which they dealt. To write an exhaustive paper or treatise on any given subject is doubtless a more difficult task than to relate a case which may have a bearing on some of the points connected with that subject, yet one who chose the easier task would be listened to with greater interest by a body of scientific men than he who wearied patience by repeating that which is to be found in the medical text-books.

Whether or not the Society acted wisely in deciding not to allow any of the papers to be published in the medical journals until they shall have been printed in the volume of Transactions can better be determined after two or three years' trial, but usually proceedings which are published only in a volume of Transactions are buried to general view, and thus injustice is done to those who have spent much labor and time in preparing them.

R. C. S.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held November 25, 1885, the President, JOHN A. WYETH, M.D., in the chair.

TOXIC EFFECTS OF COCAINE.

Dr. H. J. BOLDT said that some time ago, having encountered serious symptoms apparently from the use of cocaine, he determined to experiment with the drug upon animals. In the presence of Dr. Spitzka and others he injected eleven minims of a thirty-three-per-cent. solution of cocaine into a cat weighing seven and a half pounds. The first effect was upon the gait, which was somewhat leaping, with dragging of the hind extremities. Soon there followed convulsions, perhaps forty in number, and twelve minutes after the injection death took place. The respiration simulated the Cheyne-Stokes respiration. Just after death the rectal temperature was 104°.

The autopsy, which was made half an hour after the cat ceased to breathe, showed intense congestion of the vessels of the pia mater of both brain and cord. There was an extravasation of blood in the fourth ventricle, and also a small extravasation in the anterior part of the medulla, and minute extravasations throughout the brain.

The lungs were collapsed, contained no blood; the right ventricle of the heart was overdistended with blood, while the left was empty. Death had apparently taken place from paralysis of the respiratory centre. The gray substance of the cord resembled a bloody sponge.

Dr. PUTNAM JACOBI would suppose the phenomena mentioned by Dr. Boldt pointed rather to contraction of the blood-vessels from vaso-motor irritation, such as occurred during the local effects of cocaine, and it would seem that death occurred from secondary obstruction to the circulation in the right side of the heart following contraction and obstruction of the pulmonary vessels.

The PRESIDENT said that, all the capillaries throughout the body being affected, the heart became paralyzed: first, the right ventricle, because it was the weaker. He also remarked that respiratory and cardiac shock was more likely to occur from invasion of the surface in the neighborhood of the fifth nerve than in any other locality. He further directed attention to the danger of using chloroform or ether after cocaine. A distinguished surgeon had lost a patient by giving chloroform after the unsuccessful use of cocaine, and this surgeon had cited another case in which death followed the use of ether, cocaine having first been employed unsuccessfully.

Dr. CARPENTER said this Society had already expressed its opinion in most positive terms against the use of chloroform as an anæsthetic.

Dr. PRUDDEN said the lungs of a cat as compared with the human lung were very white normally, and fell back from the chest-walls on removing the sternum.

CARCINOMA OF THE UTERUS.

Dr. R. VAN SANTVOORD presented the uterus, the seat of cancer which had probably developed primarily in the cervix, affecting the body of the organ secondarily. The woman had been delivered of a child three days before death, being attended by a midwife. At the autopsy pigmentation was found in the omentum, intestines, retro-peritoneal glands, and broad ligament. The uterus was firmly fixed, the body of about twice the normal size. The cervix was entirely eaten away by the malignant process. The urethra, near its entrance into the bladder, was ulcerated. The vagina, endometrium, and uterus were infiltrated. The pelves of the kidneys were distended, and one contained considerable clear urine.

TUBERCULOSIS OF THE PHARYNX.

Dr. VAN SANTVOORD also presented a specimen illustrating tuberculosis of the pharynx

occurring in a child about two years of age, which was admitted to Randall's Island Hospital about four months before death, with a mass of enlarged glands under the angle of the jaw upon each side. There was cachexia, which increased; and two and a half months before death there was slight cough, and some râles were heard over the chest. About four days before death the house-physician thought the child had some difficulty in swallowing, and the larynx was observed to be covered with a thin grayish coating; the temperature was 102.5°. Death took place from exhaustion. At the autopsy the enlargements in the neck were found to be due to caseous change in the lymphatic glands. The pharynx presented a roughened, somewhat worm-eaten appearance, with lenticular ulcers of the mucous membrane. The same roughened appearance was observable on the uvula, which was thickened, and also on the mucous membrane lining the nasal cavities. There were two small ulcers upon the posterior surface of the larynx, and miliary tubercles were found in the lungs, upon the pleural surfaces, in the spleen, liver, and kidneys. There were several tubercular ulcers in the intestines, and the retro-peritoneal glands formed a mass, breaking down from cheesy degeneration.

Dr. Van Santvoord said Dr. Mackenzie, of London, had reported a number of cases of tubercle of the pharynx, and had expressed the opinion that the disease was less rare than was generally supposed, it probably being often mistaken for syphilitic disease.

Dr. DELAVAN said with regard to tuberculosis of the pharynx that it certainly was a rare affection, although there may have been many cases overlooked by the general practitioner or mistaken for syphilitic disease. He had seen three cases. Dysphagia in one of those cases was very great.

HOG-CHOLERA.

Dr. VAN SANTVOORD then presented the stomach and large intestine, being specimens which illustrated the lesions of hog-cholera. The stomach was the seat of gastritis, and of one ulcer, such as were found in numbers in the large intestine, and which constituted in that locality the characteristic lesion of cholera. The ulcer had a dark, dirty, sloughing centre, with elevated edges. The ileo-cæcal valve was swollen, showed irregular breaking-down ulcers, and for about ten inches above the gut was intensely hyperæmic, and the entire mucous membrane was sloughing in its superficial portion. In the descending colon were enlarged solitary follicles, with depressed, slightly ulcerated centres, which also showed distinctly upon the peritoneal surface.

He had found lesions in the brain and cord in two cases, in two there was broncho-pneumonia, and in all there was some œdema of the lungs. In one there were ecchymoses under the pericardium and endocardium; in one there was peri-hepatitis; in all there was enlargement of the mesenteric and retro-peritoneal glands; in one case there were a few small nodules in the kidney and liver.

Dr. PRUDDEN remarked that the facts regarding the bacteria of hog-cholera were not considered as positively settled by Koch and some other authorities. That which had been discovered by Pasteur was claimed by Koch to be identical with the bacteria found in septicæmia in rabbits.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

MEETING OF NOVEMBER 23, 1885.

The President, DANIEL LEWIS, M.D., in the chair.

IN their report the Comitia Minora recommended that Drs. A. S. Purdy and A. E. M. Purdy, against whom a verdict of five hundred dollars' damages was found last week in favor of Mrs. Brown, who claimed that they had incorrectly reported that she was suffering from varioloid, be asked to appeal their case, and, if necessary, that the Society appropriate five hundred dollars for legal expenses in fighting the case.

Dr. Piffard moved that the report be laid upon the table until further information could be given by the counsel regarding the case.

Dr. Agnew moved, as an amendment, that the matter be referred back to the Comitia with power to act in the premises. He thought that great injustice had been done to two honorable practitioners and to the medical profession (which was required under penalty of violating the law to report all cases of contagious and infectious diseases to the Board of Health) in making them liable to an action for damages of five hundred dollars for complying with the law. Nevertheless, he thought it unwise to act hastily in so important a matter or to discuss it in open meeting.

The motion, as amended, was carried.

THE PRESIDENT'S ADDRESS.

The President, in his address, rebuked those physicians who gave their testimonials to compounds issued by commercial houses, quack medicines, sanitary homes, Swedish movement cures, etc. In the city of New York there was a physician to every four hundred and fifty of the population, and it was not to be wondered at that young physicians found it necessary to invent a new splint, to run for coroner, to start a new life-insurance company, to get their names on a dispensary-staff, in order to find a few patients. As he had stated in a former address, the remedy lay in rendering admission to the medical ranks more difficult, which could

only be done by raising the standard of medical study, increasing the course, and by establishing a State Medical Examining Board.

THE MECHANICAL AND OPERATIVE TREATMENT OF KNOCK-KNEE AND BOW-LEG DEFORMITIES; WITH A DESCRIPTION OF NEW FORMS OF APPARATUS AND NEW OPERATIONS.

Dr. M. Josiah Roberts called attention in his paper to the fact that many persons in both the higher and lower walks of life had minor degrees of the deformities under consideration, for which they had sought treatment, but had been turned away by the surgeon with the statement that it was only a comparatively trifling matter, and that nature would probably effect a cure. In the author's opinion, no case in which the patient thought his deformity sufficient to justify him in seeking relief should be turned away without treatment. If nature could effect a cure in some instances, mechanical measures would do the work better and in a much shorter time.

He then exhibited drawings and photographs representing knock-knee and bow-legs, either simple or in combination with various other deformities. He then exhibited a form of splint which had been employed by Dr. Davis for the cure of in-knee by exerting constant outward pressure upon the condyles. Dr. Roberts's modification of the splint used by Dr. Davis consisted in substituting elastic for rigid pressure. He also exhibited a double splint with a movable joint, by which the same object was accomplished, but taking the weight of the body off the foot. Speaking of operative measures, Dr. Roberts described the action of the osteoclast and a simple but efficient apparatus which he had devised for causing fracture of the bone by mechanical pressure. The method consisted in placing the deformed bone between two boards and applying pressure at the point of greatest convexity by means of a wooden screw. In view of improved methods of operating, the use of the osteoclast was no longer justifiable. As to chisels, Dr. Roberts had secured those of the best form and quality, but had been unable in a large number of experiments to cut out a wedge-shaped piece of bone in a clean, workmanlike manner, and he defied any surgeon to do so, either on the living subject or on the bone denuded of flesh. As to the cross-cut saw, the strokes had to be short, the teeth became clogged, and the operation was very tedious and unsatisfactory.

Dr. Roberts then exhibited the working of the electro-osteotome, by which he was enabled to divide the hardest of bones, the tibia of the sheep, in three seconds. The instrument was now so far improved that it was entirely under the control of one hand, leaving the other hand free during the operation. It had an Edison electric lamp and mirror, by which a flood of light might be cast upon the part at will. With it the circular or the cross-cut saw, or a gouge, could be used.

Among the recent instruments of precision invented by Dr. Roberts was one for measuring and recording simultaneously any combination of angles which could be assumed at a given articulation in the human body, and another for determining the base of a wedge-shaped piece of bone necessary to be removed for overcoming a deformity of any degree. The exactitude with which the latter instrument did its work had been tested in many instances aside from operations on the human body.

A letter from Dr. Janes, of the Health Board, again called the attention of physicians to the fact that the Willard Parker Hospital, for the reception of cases of certain contagious diseases, was open. The fact seemed not to be generally known, or, at any rate, the number of cases received had not been great.

REVIEWS AND BOOK NOTICES.

ARCHIVES OF OPHTHALMOLOGY. Edited by Dr. H. KNAPP and Dr. C. SCHWEIGGER. Vol. XIX., Nos. 2 and 3. G. P. Putnam's Sons, New York.

These two numbers appear bound together, and are issued in the excellent style which is characteristic of this quarterly. The following list embraces the contents: 1. Myxosarcoma of the Optic Nerve, by Drs. Johnson and Prudden. 2. A Case of Acute Inflammation of the Lachrymal Gland. 3. Severe Orbital Cellulitis the Result of the Passage of Bowman's Probe in the Nasal Duct. Both of these cases are reported by Dr. John F. Fulton. 4. Evisceration of the Globe, by Dr. E. L. Holmes. In this operation the contents of the eyeball are removed, leaving the sclerotic and optic nerves behind. 5. Ophthalmometry, by Dr. Swan Burnett. This article gives the details of some experience with the Taval and Schiötz instrument. 6. Blindness following the Attempted Extraction of the Left Upper Canine Tooth, reported by Dr. Burnett. The retinal changes resemble those seen in cases of blindness from erysipelas. 7. Injury to the Eye from Lightning, by Dr. Laker. 8. Metastatic Sarcoma of the Choroid, by Pflüger. 9. Exophthalmus, by Dr. Suttler. 10. Removal of a Piece of Steel from the Eye by an Electro-Magnet, by Dr. Stevens. 11. Examination of the Refraction and the Dynamic Relations of the Lateral Muscles in Girls, by Beselin. 12. Resection of the Optic Nerve, by Prof. Schweigger. 13. The Measurement of the Degree of Anæsthesia produced by Cocaine, by Dr. Lucien Howe, of Buffalo. This is an account of some

researches made in the laboratory of Prof. Zuntz, of Berlin. Starting with the principle that irritation of a sensitive nerve increases the blood-tension, Dr. Howe cocained the eyes of rabbits, and then measured the blood-pressure while various forms of irritation were employed. 14. A Case of Morgagnian Cataract, by Nordman. 15. Partial Embolism of the Anterior Centralis Retinæ, by Professor Schnabel and Dr. Sachs. 16 Nine Cases of Employment of the Magnet for Removal of Iron Fragments. 17. A Case of Evisceration of the Eyeball followed by Orbital Cellulitis. Both of these are reported by Knapp. The usual Reports on the Progress of Ophthalmology, with Book Reviews, follow.

H.

A Guide to the Practical Examination of Urine, for the Use of Physicians and Students. By James Tyson, M.D. Fifth Edition, Revised and Corrected, with Colored Plates and Wood Engravings. Philadelphia, P. Blakiston, Son & Co., 1886. Cloth, 12mo. Pp. 249.

The several editions of this useful manual succeed one another quite rapidly, showing that it retains favor with the profession; and, with the care given to the revision, and the constant additions made by the author, there seems to be no reason why it should not eventually pass through as many editions as a modern French romance. It is especially adapted for ready reference, the processes being selected with reference to the wants of the busy practitioner, and the criticisms upon the comparative availability of different processes seem to be conscientiously made from personal experience. The recent delicate tests for albumen are described, but the author expresses his preference for the clinical method of boiling the urine in a test-tube and acidulating with a small amount of nitric acid, which is sufficiently accurate when checked by a second method, in which the nitric acid is poured in first and overlaid by the urine. It might be advisable to introduce in a future edition a section upon the detection of some medicinal or toxic additions to urine, such as alcohol, salicylic acid, carbolic acid, arsenic, lead, etc.

Practical Surgery: Including Surgical Dressings, Bandaging, Fractures, Dislocations, Ligature of Arteries, Amputations, and Excisions of Bones and Joints. By J. Ewing Mears, M.D. With Four Hundred and Ninety Illustrations. Philadelphia, P. Blakiston, Son & Co., 1885. 12mo, cloth, pp. 794. Second Edition.

This handsomely-printed text-book is appropriately and gracefully dedicated to the late Professor Gross, with whom the author was intimately associated for several years in his duties as Demonstrator of Surgery to Jefferson Medical College.

Seven divisions constitute the work before us, which is clear in its language in its direction for applying the various forms of dressings and for performing the various operations. Surgical Dressings, Bandaging, Fractures, Dislocations, Ligature of Arteries, Amputations, and Excision of Bones and Joints comprise the subjects, which are considered systematically and in detail, without apparently omitting any point of real importance. The illustrations are numerous, and are taken mainly from Gross and other standard works on surgery, and Gray's Anatomy.

Taken altogether, it is a compendious, complete, and convenient manual of practical surgery, which the student will find of real service when preparing for his examination, and to which frequent reference can be made with advantage when he is subsequently brought face to face with the exigencies of daily practice.

An Atlas of Clinical Microscopy. By Alexander Peyer, M.D. Translated and edited by Alfred C. Girard, M.D., Asst.-Surg. U.S.A. First American, from the Manuscript of the Second German Edition, with Additions. Ninety Plates, with One Hundred and Five Illustrations, Chromo-Lithographs. New York, D. Appleton & Co., 1885. Pp. 194.

The original work, "Microscopie am Krankenbette," by Peyer, was a book which grew rather than was made. It grew out of the habit which the author had formed of making drawings of microscopic preparations while he was studying, until he found himself in the possession of over four hundred microscopical drawings, representing principally investigations in urine, expectoration, intestinal contents, and blood. The plates, almost without exception, represent original drawings, and are beautifully executed, many of them in colors. The book consists of nine parts, giving the results of examinations of (1) the blood, (2) the mammary secretion, (3) the urine, (4) the sputum, (5) the intestinal contents, (6) the contents of the stomach, (7) the fluid contents of various abdominal tumors, (8) the secretions of the female sexual organs, and (9) various micro-organisms provoking disease. The work being intended as a microscopic atlas, the text has been made as brief as possible. All who are interested in clinical microscopy will be pleased with the design and execution of this work, and will feel under obligation to the author, translator, and publishers for placing so valuable a work in their hands. The plates in which are figured the various urinary inorganic deposits are especially fine, and the various forms of tube-casts, hyaline, waxy, epithelial, and mucous, are depicted with great fidelity and accuracy.

NEW BOOKS.

EPILEPSY AND OTHER CHRONIC CONVULSIVE DISEASES: THEIR CAUSES, SYMPTOMS, AND TREATMENT. By W. R. GOWERS, M.D. New York, Wm. Wood & Co. 1885.

FACTS AND MYSTERIES OF SPIRITISM: LEARNED BY A SEVEN YEARS' EXPERIENCE AND INVESTIGATION. WITH A SEQUEL. By JOSEPH HARTMAN. Philadelphia, Thomas W. Hartley & Co. 1885.

THE DISEASES OF SEDENTARY AND ADVANCED LIFE. A Work for Medical and Lay Readers. By J. MILNER FOTHERGILL, M.D. New York, D. Appleton & Co. 1885.

TRANSACTIONS OF THE TEXAS STATE MEDICAL ASSOCIATION, SEVENTEENTH ANNUAL SESSION Held at Houston, Texas, April 21, 22, 23, 1885. Austin (Texas), Printed for the Texas State Medical Association. 1885.

A REFERENCE HAND-BOOK OF THE MEDICAL SCIENCES, EMBRACING THE ENTIRE RANGE OF SCIENTIFIC AND PRACTICAL MEDICINE AND ALLIED SCIENCE. By Various Writers. Illustrated by Chromo-Lithographs and fine Wood Engravings. Edited by ALBERT H. BUCK, M.D., New York City. Vol. I. New York, Wm. Wood & Co. 1885.

LECTURES ON THE DISEASES OF THE NOSE AND THROAT. Delivered during the Spring Session of the Jefferson Medical College. By CHARLES E. SAJOUS, M.D. Illustrated with One Hundred Chromo-Lithographs, from Oil-Paintings by the Author, and Ninety-three Engravings on Wood. Philadelphia, F. A. Davis, Attorney, Publisher. 1885.

THE PRINCIPLES AND PRACTICE OF MEDICINE. By the late CHARLES HILTON FAGGE, M.D., F.R C.P. Including a Section on Cutaneous Diseases, by P. H. PYE-SMITH, M.D; chapters on Cardiac Diseases, by SAMUEL WILKES, M.D; and Complete Indexes, by ROBERT EDMUND CARRINGTON, M.D. Vol. I. Philadelphia, P. Blakiston, Son & Co. 1886.

THE PRACTICE OF PHARMACY: A TREATISE ON THE MODES OF MAKING AND DISPENSING OFFICINAL, UNOFFICINAL, AND EXTEMPORANEOUS PREPARATIONS, WITH DESCRIPTIONS OF THEIR PROPERTIES, USES, AND DOSES Intended as a Hand-Book for Pharmacists and Physicians and a Text-Book for Students. By JOSEPH P. REMINGTON, Ph G With nearly Five Hundred Illustrations. Philadelphia and London, J. B. Lippincott Company. 1885.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY. Eighteenth Annual Meeting, Pequot House, New London, Connecticut, July 14, 1885. Vol III. Part IV. Published by the Society. Mercury Publishing Company, Printers, New Bedford, Massachusetts. 1885.

STUDENTS' AID SERIES:

AIDS TO GYNÆCOLOGY. By A. A GUBB, L.R C.P., etc New York and London, G P. Putnam's Sons. 1885.

AIDS TO MEDICINE. Part III. (Double Part) Diseases of the Brain and its Membranes, of the Nervous System, of the Spinal Cord, and of the Ear. By C. E. ARMAND SEMPLE, B.A., etc. New York and London, G. P. Putnam's Sons. 1885.

AIDS TO SURGERY. By GEORGE BROWN, M.R.C.S., etc.

AIDS TO OBSTETRICS. (Double Part.) By SAMUEL NALL, B.A., etc. New York and London, G. P. Putnam's Sons, 1885.

NEW REMEDIES AND CLINICAL NOTES.

THE LIFE-HISTORY OF FAT-CELLS.—A study of the structure, mode of development, and retrograde metamorphosis of fat-cells, undertaken by Bobritzky, has recently given some interesting results, which are communicated to the *Centralblatt für die Medicinischen Wissenschaften*, No. 43. The investigation was conducted upon mammalia, batrachia, and crustacea, in the laboratory of Prof. Kutschin, in Charkow. His conclusions are as follows:

1. The fat-cells of rabbits, when in indifferent fluids (weak iodine or sodium chloride solutions), afford good objects for the study of the structure of these elements.

2. Fat-cells have no proper membrane, but in its place there is an external protoplasmic layer, which becomes condensed following pressure upon the sides of the drop of fat.

3. Argentic nitrate gives good results when used as an interstitial injection, but it cannot be regarded as the specific reagent for the study of the structure of the fat-cells, because other reagents used for interstitial injection afford equally good preparations.

4. Chlor-palladium, which the author had been the first to apply to the study of the structure of the fat-cells, offers proportionately the best results, and he had been led to prefer it to all other reagents, and could recommend it to other investigators.

Usually he employs a weak solution, light yellow in color (1 gm. to 600 to 800 ccm.), not only for interstitial injection, but also for staining small pieces of adipose tissue by laying them directly in the reagent, by which the fat-cells are colored yellow. By this manipulation the parts of the cell (*i.e.*, the condensed peripheral layer, the finely granular protoplasm, with one or two nuclei, and the drops of fat) clearly appear; but also the clear transparent fluid can easily be recognized, which is found between the protoplasm and the drop of fat.

5. This clear transparent solution in the fat-cells, which usually is observed in all methods of examination of adipose tissue, is, however, an artificial product, which is formed by the diffusion of the reagent solution through the limiting membrane of the cell. (This view is demonstrated in the clearest manner by a comparison of the fresh fat-cells of the rabbit with those after treatment with chlor-palladium.)

6. Every fat lobule has its proper, characteristic, and entirely-closed vascular system.

7. In adipose tissue no nerve-endings are to be found.

8. The opinion of a few investigators (Fohmann, Arnold, Klein, etc.) that the adipose tissue is to be counted with the lymph system is without foundation. This conclusion was probably attained after a study exclusively of the fatty tissue in the omentum and mesentery, where naturally there are many lymphatic vessels to be found.

9. The fatty tissue is developed from special peculiar elementary forms, but not from connective-tissue cells. This view of the development of fat-cells proceeds from observations made upon embryos in which are found some elements in which are seen fine granular protoplasm with a clearly-defined nucleus. These elements can usually be observed at

the places corresponding with the locality of the future fatty tissue. These can be confounded neither with wandering cells (which may be distinguished by their smaller size and less finely granular protoplasm) nor with Waldeyer's plasma cells (which are seldom found, do not form groups, and are rather smaller).

10. Fat-cells are not bound together by protoplasmic processes, as Fleming has described.

11. Atrophy of fat-cells is a result not only of fasting, but also of morbid processes. It indicates an anomalous (abnormal?—Tr.) condition of the animal organism.

12. The disappearance of fat in the atrophy of adipose tissue begins in the group of fat-cells lying most distant from the arteries, on account of want of nutriment sufficient to nourish all the fat-cells in the entire lobule.

Treatment of Carbuncle.—Referring to Dr. Bulkley's treatment of carbuncle by the application of extract of ergot, oxide of zinc, and simple ointment, and the administration of a ferro-saline mixture and calcium sulphide, the editor of the *Medical and Surgical Reporter* says that he has been in the habit of treating carbuncle in a different manner, which, however, has invariably given the best results when used in recent cases. "As soon as the initial induration announces the beginning formation of a carbuncle, from two to ten European leeches (their number depending upon the size of the carbuncle, the intensity of the inflammation, and the age and general condition of the patient) are at once applied to the indurated and reddened skin. Should it be impossible to procure leeches in time, then the antiphlogistic touch is thoroughly practised, by which is meant scarifying the parts with the point of a sharp, thin blade. Immediately after the tincture of iodine is liberally applied every three or four hours, and the part covered with absorbent cotton. Frequently the formation of pus is thus totally avoided, or, should it nevertheless occur, limited to a very small quantity. As soon as the symptoms indicate the threatening presence of pus, one small but deep incision is made, and poultices sprinkled over with Goulard's extract then take the place of the dry cotton. As soon as the pus appears upon the surface, a two-per-cent. solution of carbolic acid and water is injected every five hours into the opening, and unguent. zinci benzoatis (oxidi?), also containing two grains of carbolic acid to every one hundred grains of salve (or about nine to ten grains to the ounce), applied locally." Under this treatment it is claimed that the carbuncle either disappears by the fifth or the sixth day, or, if pus form, by the ninth or tenth day, without having given rise to any great constitutional disturbance. Internally, tonics are resorted to only when debility of the patient indicates the necessity.

Calcined Alum in Intermittent Fever.—The use of alum is not new in the treatment of malarial affections, but the possibility of its employment in place of the costly cinchona salts gives it some claim on our attention. Dr. F. Uhle, a surgeon of the Dutch army stationed at Sumatra, gives his experience with the drug in three hundred and sixty cases treated in 1884. The usual dose of dried alum was fifteen grains, the last one being taken one hour before the usual time of accession of temperature. In remittent fever it was given in the afternoon. The daily amount varied with the fever. The higher the fever and the longer the access, the larger the dose. The largest amount in one day was six grammes, while the same results were obtained in others by two grammes. Smaller doses are not effective. In twenty-two cases he reported seventeen successes; five failing. After the chills have stopped, decreased doses of the remedy should be given for a few days.

In the five unsuccessful cases there were grave intestinal complications in two, in two others there was a continued fever, and the fifth had hectic.

Finally, it is evident that alum may replace quinine, at a less price, with better taste, and without producing disagreeable effect,—at least in pure intermittents. What the character of the other cases may be that are best treated by alum remains to be demonstrated by further observation and experiment.—*Bull. Gén. de Thérapeutique*, September 15.

Recurrent Laryngitis.—Prof. E. Fletcher Ingals, in a paper read before the Illinois State Medical Society, calls attention to the relation of cause and effect existing between recurring attacks of laryngitis and obstruction of the nares, or ordinary catarrh, and makes practical suggestions as to treatment. He concludes as follows:

1. Recurrent laryngitis is usually dependent upon obstruction of the nasal cavities.

2. This obstruction, in the majority of cases, is caused either by deflection and thickening of the septum, or by what is known as hypertrophic catarrh.

3. To effect a permanent cure the obstruction must be removed.

4. The operative procedures necessary for the removal of these obstructions may be made painless by the use of hydrochlorate of cocaine.

5. This method of treatment, properly carried out, may be relied on to cure the catarrh and the laryngitis which it has caused.

6. Great improvement in the general health often results from the removal of the nasal obstruction.

7. In acute colds or exacerbations of hy-

pertrophic catarrh, immediate relief may be obtained by the insufflation of small quantities of cocaine.

The lecturer, in the treatment of acute colds, uses cocaine, four parts; starch, sugar of milk, ninety-six parts, in fine powder. A small quantity to be blown into the nares at bedtime.— *Jour. Amer. Med. Association*, December 5.

Treatment of Cholera by Enteroclysis.—During the epidemic of cholera in Naples last year, Prof. Cantani had abundant opportunity of witnessing the effects of a method of treatment which he highly recommends (*Il Morgagni*), by copious tannin injections into the blood and warm saline hypodermic injections. He considers an attack of cholera to be divided into two marked stages,—1, of infection; 2, of intoxication. The slowing and final arrest of the circulation is due to cardiac failure and progressive thickening of the blood. In order to prevent this, he proposes replacing the water lost by hypodermoclysis. Attaching great importance to the development of ptomaines in the intestinal tract, he considers that the poisonous process is efficiently checked by copious enemata of astringent and antiseptic solutions. The amount of fluid must be large enough to pass the ileo-cæcal valve and irrigate the small intestine. The solution he employs varies in strength from one per cent. to two grammes of tannic acid to the pint of water, at a temperature of 39° to 40° C. (104° F.).

Valerianates in Melancholia. — Dr. S. A. De Foe, of Washington, New Jersey, writes to the *Medical Brief* that a combination of the valerianates of zinc, iron, and quinine works like a charm in cases where fretfulness and worry threaten to develop chronic melancholia. He used Schieffelin & Co.'s soluble gelatin-coated pills, containing one grain of each of the above-named salts. Having tried this formula in many cases, he pronounces it a specific for the worry of nervous women, melancholia, and incipient insanity.

MISCELLANY.

The International Medical Congress of 1887.—A meeting of members of the medical profession interested in the International Medical Congress in 1887, to which prominent medical men from a number of cities were invited, was held at the hall of the College of Physicians, Philadelphia, December 4, 1885, Dr. D. Hayes Agnew in the chair.

It was stated that official notice had been given of the election, as members of the present Executive Committee of the Congress, of Drs. J. S Billings and J. M. Browne, of Washington, District of Columbia; Christopher Johnston, of Baltimore; George J. Englemann, of St. Louis; and J. M. Da Costa and William Pepper, of Philadelphia.

A general and strong expression of opinion was made in support of the American Medical Association and its Code of Medical Ethics, and sincere regret was expressed that hasty action on the part of the Association, and the introduction of false issues, had imperilled the success of the Congress. It was made entirely evident, however, that the acceptance of the above elections would not be regarded as affording any adequate guarantee for the future scientific conduct of the Congress, and consequently would not be followed by any co-operation on the part of the leading members of the profession now unwilling to join in that work. As an evidence of the earnest desire which is felt for the restoration of harmony upon this subject, and for the reorganization of the Congress on a basis which would command general support, and thus insure success, the view was unanimously expressed that if the present Executive Committee should unite with them the Original Enlarged General Committee, and recommence the organization *de novo*, this course would insure the desired result.

Kansas City Medical Index.—A change has been made in the editorial staff of this progressive Western journal. Drs. Browning, Drake, and Adams have retired, and Dr. John W. Elston, the founder of the periodical, has associated with him editorially Dr. Emory S. Lamphear, who has already had considerable experience in medical journalism. We wish the *Index* success in its efforts to elevate and unify the profession and to establish medical societies and local sanitary boards in its neighborhood. We are glad to see that it advocates the International Medical Congress at Washington in 1887.

Colden's Beef.—Dr. Wm. Alex. Greene, Macon, Georgia, writes that he has tested the virtues and efficiency of "Colden's Liquid Beef Tonic" in his private practice in cases of general debility, weakness, depression, dyspepsia, loss of appetite, and nervous affections, when medicine had proved more than useless. He found it the best remedy he had ever used in chronic alcoholism, when the stomach is always irritable, and food is required to nourish and invigorate the drooping strength and nervous depression.

Mütter Lectures at the College of Physicians —Dr. Henry F. Formad will deliver a series of lectures before the College of Physicians, commencing December 8, and ending January 15, on successive Tuesdays and Fridays (except during Christmas week), at 8 P.M., on the Mütter foundation. Sub-

jects—"Morbid States as influenced by Embryonal Development, Anomalous Structural Peculiarities, Injuries, and the Effects of Lower Organisms, with Special Reference to Surgical Pathology."

THE PHILADELPHIA POLYCLINIC will remove in the early spring to its new and much larger building, Broad and Lombard Streets, where it is expected to open a hospital in addition to the dispensary service used for clinical instruction. The class of practitioners this year has been unusually large. *The Polyclinic Journal*, edited by the faculty, will be increased in size after January 1.

PEPTONIZED BEEF.—It would appear that the problem of an extractive of digested beef has been solved by Prof. Preston B. Rose, formerly of the Michigan State University. The general agents of this preparation, Messrs. Chapman, Green & Co., of Chicago, will be pleased to forward samples, as per their advertisement.

THE *Illustrirtes Monatsschrift der ärztlichen Polytechnik* in its November issue and succeeding numbers will publish an illustrated report of the Strassburger Erfindungs Ausstellung, which will undoubtedly be interesting and valuable. The *Monatsschrift* is published at Berne, and can be obtained from the publishers.

A RECEPTION to the members of the Philadelphia County Medical Society will be given on the evening of December 12, by the President of the Society, Dr. R. J. Levis, at his residence, Sixteenth and Walnut Streets.

BARRY'S self-registering clinical thermometers are well made, accurate, and reliable. They can be sent by mail.

DR. CHARLES WIRGMAN has been elected one of the staff of attending physicians to the Jefferson Medical College Hospital.

DR. JOHN H. PACKARD has removed his office and residence to No. 1437 Spruce Street.

NOTES AND QUERIES.

MEMORANDUM CONCERNING THE CORROSIVE-SUBLIMATE TREATMENT OF CHRONIC ECZEMA OF THE SCALP.

(WRITTEN BY BENJAMIN PARKER, A.M., M.D., WHEN OVER EIGHTY YEARS OF AGE, APRIL 4, 1842.)

Contributed by his grandson, Dr. W. Thornton Parker, Newport, Rhode Island.

"The scald head is *cured* in a few days by the following method: After cutting the hair as close as possible, wash the head every morning with soapsuds, then sprinkle on white precipitate with a bunch of cotton, like hair-powder, until it is all white. Go through this process every morning until the head is well, which will be in a fortnight. If the case is inveterate, give bark and wine during the local application. *Probatum est.*

"Sometimes a weak solution of corrosive sublimate is used to great effect. In very bad cases it is found to be more effective."

INTERNATIONAL MEDICAL CONGRESS: ACTION OF THE CAMDEN COUNTY MEDICAL SOCIETY.

At the semi-annual meeting of the Camden County Medical Society, held November 10, 1885, the following resolutions were unanimously adopted:

Resolved, That this Society approves of the action of the American Medical Association in enlarging the committee of arrangements for the Ninth International Medical Congress, in 1887.

Resolved, That the rules regulating the membership and business of the Congress adopted by the committee of arrangements at the meeting in New York, September 3 and 4, and the transference of the future management of the Congress to an executive committee, composed of the President of the Congress, the Secretary-General, the Treasurer, the Chairman of the Finance Committee, and the Presidents of Sections, be considered by this Society sufficient to silence criticism and enlist the sympathies and support of the profession throughout the United States.

Resolved, That the Secretary be instructed to forward copies of these resolutions to the County Medical Societies of New Jersey.

E. B. WOOLSTON,
President.

H. GENET TAYLOR,
Secretary.

CAMDEN, NEW JERSEY, November 10, 1885.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM NOVEMBER 22, 1885, TO DECEMBER 5, 1885.

MAJOR R. S. VICKERY, SURGEON.—Relieved from the assignment as Acting Medical Director, Department of Colorado, to date from the 16th inst. S. O. 200, Department of Colorado, November 23, 1885.

CAPTAIN C. K. WINNE, ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon, Benicia Barracks, and Attending Surgeon at Benicia Arsenal, California. S. O. 109, Department of California, November 20, 1885.

CAPTAIN WALTER REED, ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply for one month's extension, to take effect about December 1, 1885. S. O. 115, Department of the Platte, November 18, 1885.

CAPTAIN ARTHUR W. TAYLOR, ASSISTANT-SURGEON.—Granted leave of absence for one month, to take effect December 5, 1885. S. O. 116, Department of the Platte, November 20, 1885.

FIRST-LIEUTENANT A. R. CHAPIN, ASSISTANT-SURGEON.—Ordered for temporary duty at Fort Robinson, Nebraska. S. O. 115, Department of the Platte, November 18, 1885.

LIEUTENANT-COLONEL JAMES SIMONS, U.S.A. (retired).—Died November 11, 1885, at Baltimore, Maryland.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM NOVEMBER 22, 1885, TO DECEMBER 5, 1885.

R. A. MARMION, SURGEON.—Detached from Marine Barracks, Washington, D.C., December 7, and wait orders.

A. M. MOORE, SURGEON.—Ordered to Marine Barracks, Washington, D.C., December 7, 1885.

HAMPTON AULICK, SURGEON.—Ordered to the "Alliance" as relief of Surgeon George P. Bradley.

GEORGE P. BRADLEY, SURGEON.—Ordered to Naval Hospital, Philadelphia.

JOSEPH SHAFER, ASSISTANT-SURGEON.—Detached from Naval Hospital, Philadelphia, and ordered to the "Minnesota."

J. H. GAINES, PASSED ASSISTANT-SURGEON.—Detached from Naval Hospital, Philadelphia, and ordered to the "Dolphin."

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, DECEMBER 26, 1885.

ORIGINAL LECTURES.

REMINISCENCES OF EARLY HOSPITAL DAYS.

An Address delivered before the Association of Resident Physicians of the Pennsylvania Hospital on its First Annual Meeting, held in Philadelphia, December 17, 1885,

BY THOMAS G. MORTON, M.D.

MR. CHAIRMAN AND GENTLEMEN,—Let me, on behalf of the older members, congratulate all who are present upon this memorable occasion that at last we can meet together in an "Association of Resident Physicians of the Pennsylvania Hospital," thus fulfilling earnest wishes hopefully entertained and frequently expressed by so many of the older residents. We have assembled to inaugurate this, our first reunion as a Society, and the occasion should not only bring pleasure and profit to each of us individually, but indirectly, at least, should also advance the welfare of the hospital in which all of us have a deep, abiding interest.

The year 1750 marked the birth of the hospital. Although during the previous year, and perhaps even earlier, the necessity for some refuge for the insane and the sick poor must have been frequently discussed by the benevolent people of this city of Brotherly Love, the earliest public and formal demonstration for this object was the presentation of the following:

"To the Honorable House of Representatives of the Province of Pennsylvania."
"The Petition of sundry Inhabitants of said Province, which Humbly Sheweth—

"That with the Numbers of People, the Number of Lunatics or Persons distempered in Mind and deprived of their rational Faculties hath greatly increased in this Province.

"That some of them going at large are a Terror to their Neighbors, who are daily apprehensive of the Violences they may commit; And others are continually wasting their Substance, to the great Injury of themselves and Families; ill-disposed Persons wickedly taking Advantage of their unhappy Condition, and drawing them into unreasonable Bargains, etc.; That few or none of them are so sensible of their Condition as to submit voluntarily to the Treatment their respective Cases require, and therefore continue in the same deplorable State during their Lives: whereas it has been found by the Experience of many Years that above Two-Thirds of the Mad People received into the Bethlehem Hospital, and there treated properly, have been perfectly cured.

"Your Petitioners beg Leave farther to represent, That the good Laws of this Province have made many compassionate and charitable Provisions for the Relief of the Poor, yet something farther seems wanting in favor of such, whose Poverty is made more miserable by the additional Weight of a grievous Disease, from which they might easily be relieved if they were not situated at too great a Distance from regular Advice and Assistance, whereby many languish out their Lives, tortured perhaps with the Stone, devoured by the Cancer, deprived of sight by Cataracts, or gradually decaying by loathsome Distempers, who, if the Expense in the present Manner of Nursing and Attending them separately when they come to Town were not so discouraging, might again, by the judicious Assistance of Physic and Surgery, be enabled to Taste the Blessings of Health, and be made in a few Weeks useful Members of the Community, able to provide for themselves and Families.

"The kind Care our Assemblies have heretofore taken for the Relief of sick and distempered Strangers, by providing a Place for their Reception and Accommodation, leaves us no room to doubt their showing an equal tender Concern for the Inhabitants. And we hope they will be of Opinion with us, that a small Provincial Hospital, erected and put under proper Regulations in the Care of Persons to be appointed by this House or otherwise, as they shall think meet, with Power to receive and apply the charitable Benefactions of good People towards enlarging and Supporting the Same and Some other Provisions in a Law for the Purposes above mentioned, will be a good Work, acceptable to God and to all the good People they represent. We therefore recommend the Premises to their serious Consideration."

This petition, which is without doubt in the handwriting of Benjamin Franklin, is not signed by that distinguished man, probably from the fact that at this time he was before the people for public office (he soon after was elected to represent the city of Philadelphia in the Provincial Assembly). The wording of this petition is at once forcible and significant, not merely advocating the needs of the sick and injured, but the insane are referred to first, as if constituting the most important subject for legislation, and in a manner which is truly humane and highly enlightened. The views thus expressed on behalf of this afflicted class were certainly half a century in advance of the times, and this document remains an imperishable monument to the

honor, intelligence, and philanthropy of the originators and promoters of this charity.

There lived in Philadelphia at this period a Dr. Thomas Bond, who was born in 1712 in Maryland; afterwards coming to this city, he became one of its most distinguished physicians and citizens. Dr. Bond was a man of very great benevolence and was universally esteemed. He unquestionably was the originator of the movement to erect the hospital, and he was, as well, the founder—in 1766—of the first course of clinical lectures at this hospital, and indeed in this country. It seems eminently fitting that this great charity should owe its inception and first impulse to the efforts of a member of the medical profession. Dr. Bond belonged to a literary society with Franklin and Bartram, and doubtless the future hospital was the frequent subject of their discussions. So much interest did they take in it that it was through Dr. Bond's personal efforts that the first subscriptions were obtained. Later, Franklin becoming interested, the subscriptions increased to such an extent that the enterprise was in a position to invoke legislative assistance in order to insure its permanent success.

The petition was read in the Provincial Assembly Eleventh Month 23, 1750 (as the civil and ecclesiastical year then commenced the 1st of March, the date Eleventh Month 23 would correspond to First Month or January 23 of ordinary chronology, and it is so endorsed on the petition). The "Act for the relief of the sick poor of this province and for the reception and cure of Lunaticks" was finally passed, and on Third Month 11 (or May 11, 1751 A.D.) it finally became a law and the charter of the hospital.

This act appropriated in aid of the hospital two thousand pounds from the treasury of the commonwealth, provided a like amount could be raised by private subscription. All who gave ten pounds or upwards were made contributors. The first meeting was held shortly afterwards in the Old State-House.

This charter provided that the contributors should meet on the first Monday in May yearly, forever, and that the rules they made should be obligatory when approved by the Chief Justice of the State, the Speaker of the Assembly, and the Attorney-General. On July 6, 1751, the managers addressed the proprietaries John and Richard Penn, in England, and asked the donation of a lot of ground on the south side of Mulberry (now called Arch) Street, between Ninth and Tenth, upon which to build the future hospital. The proprietors sent a charter and a grant for the lot of ground on Sassafras (now Race) Street between Sixth and Seventh (which is now known as Franklin Square). Both charter and lot were declined; the former because they had already received a better charter from the Assembly, the latter owing to the fact that the ground offered was inconvenient and unsuitable, because, as the managers stated, it was "contiguous to the brickmakers' grounds, from which the city hath been furnished with bricks for forty years past; that there are large ponds being constantly filled with standing water, renders the neighborhood unhealthy, and of course absolutely improper for our purpose, which is to restore the sick to health." The present lot (except the Spruce Street front, to the depth of sixty feet, which was subsequently presented by the Penns) was purchased in December, 1754, for five hundred pounds. The corner-stone of this house was laid May 28, 1755, with the following characteristic inscription by Franklin:

"In the year of Christ
1755
George the second happily Reigning
(for he sought the happiness of his people)
Philadelphia Flourishing
(for its inhabitants were public spirited)
This Building
By the Bounty of the Government
and many private persons
was piously founded
For the Relief of the Sick and Miserable.
May the God of Mercies
Bless the undertaking."

In 1794, the crowded condition of the wards in the east wing (which had been occupied since its completion in December, 1756) from the "increasing number of lunaticks excluding the sick and injured," demanded more accommodations, and the west wing was then commenced. It was finished in 1796; but the central portion was not built until 1805. The lots east and west of the hospital, and south on Pine Street, were afterwards purchased for nine thousand dollars, and afterwards were sold for three hundred and twenty-six thousand five hundred dollars, which was all subsequently expended on

improving the grounds and in erecting the buildings of the Hospital for the Insane in West Philadelphia.

Before the Pennsylvania Hospital was built, a private house on the south side of Market Street, west of Fifth, had been secured and occupied through the energy of Dr. Bond, who, with his brother Phineas and Lloyd Zachary, agreed to attend the sick gratis for two years. Drs. Grame, Cadwallader, Moore, and Redman were in extraordinary cases requested to give their services.

Into this temporary hospital, which was used four years, the first two patients were admitted on February 11, 1752, the day the hospital opened. One was a lunatic, and, oddly enough, named Shines.

In 1760 there were so many insane in the hospital that "two constables were hired to keep people away from the lunatics." The insane, after removal to this house, but prior to the building of the west wing, were kept in the basement cells, and some in the second story and attic of the east wing. I found among the records this curious note:

"Thomas Perrin, an insane patient, was allowed to eat, sleep, and live in the cupola of this wing from 1765 to 1774; he never left his cramped quarters, either in summer or winter."

He was noted for his long nails and beard, his matted, dishevelled hair, and for his insensibility to cold, since "he never," the record states, "in the coldest weather of nine winters, came near to a fire."

The day-rooms for the insane, subsequent to 1826, until their removal to the new Department, were over the present stables. The women had the northern, and the males the southern portion. The exercising-yards were the present yards and a part of the front garden. After the insane were removed, in 1840, an attempt was made to use the cells for private rooms for pay-patients, but the scheme failed.

In 1808, Drs. Rush, Physick, and Barton recommended the managers to open the wall on Pine Street opposite the centre of the house, to introduce more fresh air. Dr. Wistar united in the view, "provided it can be done without depriving the insane patients of a proper place to walk in." When the Pine Street lots were sold, it was agreed with the purchasers that the Pine Street gate, then the only public entrance, should be closed.

It is satisfactory to note how charitably the early judges in this State construed the laws when the insane were charged with crimes. In 1782, Peter Lesher, of Bucks County, was tried and acquitted of murder on the ground of insanity. Chief Justices McKean, Atlee, and Bryan wrote to the managers with regard to this patient, "As his insanity still continues, and he is not yet eighteen years of age, and has frequent lucid intervals, we are of the opinion that he may be restored to his reason by proper management."

Numerous instances are on record when the insane were brought to the hospital having been acquitted of murder and other high crimes, as "insane by visitation of God," and ordered to be kept in the hospital "until it shall please God to restore them." The insane were detained simply on the certificate of a physician.

Dr. Rush, who was elected one of the physicians in 1783, and served until 1813, was one of the most notable men of his time. He was surgeon-general of the Revolutionary army, member of Congress, one of the signers of the Declaration of Independence, and first treasurer of the first United States Mint. Dr. Rush made several attempts to ameliorate the treatment of the insane in this hospital. Their condition too often was wretched, and the care given to them was miserably inadequate. Dr. D. Hack Tuke, in his book just published, entitled "The Insane in the United States and Canada," London, 1885, gives a biographical sketch of Dr. Rush, who is referred to as "a remarkable physician and excellent man," known as "the American Sydenham." Dr. Tuke calls him the "American Fothergill." Dr. Tuke says, "I am not aware that there is anything which shows that he [Rush] was struck with the inadequate provision made for them [the insane], or their miserable state at that time in gaols and almshouses, and even in the cells of the basement of the Pennsylvania Hospital in Philadelphia. These receptacles survive as relics of the past to indicate the wretched provision made for maniacs in those days."

Among the papers which I recently discovered is a letter of Rush's to the managers, written in November, 1789, which shows that Dr. Rush had the care of the insane more at heart than Dr. Tuke has

credited him with having. In this letter Dr. Rush says,—

"Under a conviction that the patients afflicted by madness should be the first objects of the care of a physician of the Pennsylvania Hospital, I have attempted to relieve them, but I am sorry to add that my attempts, which at first promised some success, were soon afterwards rendered abortive by the cells of the hospital.

"These apartments are damp in summer, and too warm in winter. They are, moreover, so constructed as not to admit readily of a change of air: hence the smell of them is both offensive and unwholesome.

"Few patients have ever been confined in these cells who have not been affected by a cold in two or three weeks after their confinement, and several have died of consumption in consequence of this cold.

"These facts being clearly established, I conceive that the appropriating of the cells any longer for the reception of mad people will be dishonorable both to the science and humanity of the city of Philadelphia.

"Should more wholesome apartments be provided for them, it is more than probable that many of them might be relieved by the use of remedies which have lately been discovered to be effective in their disorder."

During the early history of the hospital the more violent insane, as was universally the custom, were harshly controlled. Among the old papers I found a bill from John Cresson, dated 3d mo. 7, 1752, against "ye Hospital for a pair of hand-cuffs, and for 2 legg locks, and 2 large rings and 2 large staples, 5 links and 2 large rings and 2 swifells for leg chains;" and that this mode of restraint was customary is shown by two letters from a patient to the managers. In the first, dated September 20, 1782, the writer says, "I am confined here in chains at the instance of a relation of my wife's. I hope you will desire the steward to unchain me, but as his duty he could not do less." On September 25 he again writes, "The present serves to inform you that, pursuant to your orders, I am unchained." Mr. Wm. G. Malin, who is, I am glad to say, with us this evening, and whose hospital life dates from 1825, says that he remembers but few instances, however, during this early period where chains were used, and that, although these were made of metal, they were covered with leather. Although the Pennsylvania Hospital early in its history naturally followed the prevailing custom, which harshly coerced the more violent cases, we should likewise remember that in this house nearly seventy years ago, far in advance of the times, were introduced those enlightened and humane views which later became generally accepted, and which make amusements, occupation for mind and body, consideration and kindness, with the absence of mechanical restraint, the basis of the treatment of this most afflicted class.

The very remarkable influence which this hospital, even in its early days, exerted for good in the community was due to the combined efforts of the managers and their officers, whose wisdom, broad charity, and integrity have never been brought in question; and I may be permitted to say that the constant personal attention of the managers, and their recognized care in the selection of the medical appointments, have made an enduring name for this institution.

The "seal" of the hospital, made upon Franklin's suggestion, in 1752, represents the Good Samaritan, and is simply a typical representation of what the hospital has been doing for the past one hundred and thirty-five years.

As early as 1752 we find a curious resolution, which shows the care the managers attempted in the selection of its officers:

"That the physicians of the hospital, or such practitioners as are to perform operations, shall first give demonstrations of their skill and abilities in anatomy operations, dressings, and bandage, before the managers, and such others as the managers may think fit to join with themselves to assist in judging of the performance of such practitioners."

It is probable that this resolution was never carried out. The rules also for patients, made in 1752, were probably more stringent than the application of them, for in May, 1752, the first surgical case admitted (an encysted tumor) was allowed to bring her infant into the hospital with her. The record in 1756 states that "a patient judged incurable, but must perish in the streets if not admitted, is therefore allowed to enter."

In 1764 a lunatic was admitted, who was taken up in the streets naked. Up to 1767 venereal diseases were admitted on the free list; after this they were made to pay. In 1777 the British for a time occupied the hospital, and this year there were no meetings of the Board of Managers for many months, four of its members having

been banished to the wilds of Virginia as Tories. The following year the inspector-general of the British army stripped the hospital of blankets, bedding, medicines, and instruments. The latter were the finest in the country, and no restitution or reparation was ever made for the losses thus inflicted.

It is curious to read in the minutes of 1804 that the managers purchased a Dutch servant-man. The record says, "The principal object the managers had in view in buying him is to employ him in the apothecary-shop, to keep it clean and in good order, and to go on such errands as may be necessary in the Medical Department."

The hospital has always been popular, and among all classes. Prior to the Revolution considerable assistance was received from the English, more especially from the Society of Friends there, who contributed largely to its funds. The earliest gift of landed property, about four acres, near Germantown, came during the first year of the hospital history, from Matthew Koplin, a German gentleman. The donor wrote to Christian Sauer, who was a Dunkard, and the founder of the first Pennsylvania newspaper, and who was a great friend of the hospital movement, that

"The proposed institution has not such a foundation nor is like to become such a hospital as I have seen and known in Germany, where great sums of alms were collected and ill used, according to the affection of the single master of the hospital, governed by self-love, enriching themselves and favoring their friends, so that they lived in plenty, superfluity, and voluptuousness, insomuch that they could keep horses and coaches for themselves like rich people, although they had nothing before, nor any income but out of the funds of the hospital, when on the contrary the poor and needy were not taken care of according to their necessity, because it was consumed otherwise."

In reply, the Board say, as a caution to future managers against such misapplications, they "have ordered this letter to be copied within their Book of Minutes, that it may be preserved to posterity as the testimony of the original intentions of the founders of this pious institution."

In 1760, a sum of money having been contributed by the acting of a stage-play, the managers in accepting this thought it necessary to give their reasons for receiving "so profane a donation."

In 1764 the celebrated Whitefield gave the hospital five pounds, and in 1765 he preached a sermon, at which more than one hundred and seventy pounds was collected and sent to the hospital.

"Rich widows and other single women" were solicited to subscribe, which they did handsomely. Jury-fines, contested sums of money, sums in the hands of trustees, assignees, and others, not claimed, and fees of various kinds were all sent here, thus showing the interest felt in the early days of the hospital. Time will only permit me to refer to some of the early gifts to the institution, the most conspicuous being that of the picture of "Christ Healing the Sick," by Benjamin West, promised by him in 1791, but which did not reach the hospital until late in 1817. Other gifts, not so valuable pecuniarily, though intrinsically beyond price, were also received. The chair in which our chairman rests belonged to William Penn. It was given to the hospital by Henry S. Drinker in 1810, and is said to have been used by the founder of Pennsylvania when giving audiences to the Indians at Pennsbury Mansion. The William Penn brass candlesticks, given about the same time by John Hulme, were unfortunately sold for old brass by a former matron. The fine marble bust of "Penn," now at the Insane Department, was presented by Traquair in 1802, and is said to have been the first executed in this country. The leaden statue which adorns the lawn in front of the hospital was given in 1804 by John Penn, the grandson of William Penn.* The excellent portrait of Samuel Coates, who served the hospital as manager from 1785 to 1825, more than forty years, was painted by Thomas Sully, and by him presented to the institution. The portrait of Sir Astley Cooper was presented by the late William R. Clapp, who was librarian for many years.

The hospital has at times sustained some unavoidable monetary losses, though in a manner over which the management had no control. Especially was this the case in the years 1779–80–81, when loans and other debts due the hospital were paid off

* The statue of Wm. Penn was originally the property of Sir Francis Dashwood, who was Lord Le Despencer from 1763 to 1781, and stood in West Wycombe Park. His successor did not admire the Founder of Pennsylvania, and sold the statue for its value as lead. It was found in a London junk-shop by a grandson of Penn, who bought it and presented it to the Hospital.

in Continental money, then so depreciated that the loss was estimated at forty thousand dollars.

From the earliest times it was the custom of the students in physic to walk the wards with the hospital physicians. In 1763 a fee was required of those who were not apprenticed to the physicians. At this time the library and the fund to support it came into existence. The physicians on May 31, 1763, state, "That as the custom of most of the hospitals in Great Britain has given such gratuities to the physicians and surgeons attending them, we think it properly belongs to us to appropriate the money arising from thence, and propose to apply it to the founding of a 'Medical Library' in the said hospital, which we judge will tend greatly to the advantage of the pupils and the honor of the institution." Such was the origin of this great collection of books, for a long time unequalled on this continent, and now surpassed by few libraries exclusively medical. It now contains fully fifteen thousand volumes, besides many pamphlets, kept in excellent condition.

The first medical book which formed the nucleus of the library appears to have been a present, in the year 1762, from Dr. John Fothergill, an English physician, highly distinguished for benevolence and professional skill, and a member of the Society of Friends. Dr. Franklin once said of him, "I can hardly conceive that a better man ever existed." This gift probably suggested the idea of establishing a medical library. Dr. Fothergill was thanked for an experimental history of the "Materia Medica," by William Lewis, F.R.S., London, 1761; and donated by him for the benefit of young students in physic.

The "Medical Fund" increased rapidly, more than was thought could then be judiciously expended in books, so that upon the suggestion of the medical board one thousand dollars was given from the fund, by the consent of the physicians, to finish the library. Eighteen hundred dollars in like manner was appropriated to complete the operating cupola-room. The apothecary-shop subsequently received fifteen hundred dollars; and thirteen hundred dollars went to purchase clothing for poor patients, for stoves, fuel, and fencing a large amount, and nearly five hundred dollars was paid to Sully for the large portrait of Rush now adorning the landing-place of the principal stairway outside the library door.

It has been a matter of consideration whether more good could not be accomplished if the library, instead of remaining here, were placed on deposit with the College of Physicians, the owner of a fireproof building in the city.

The resident physicians in olden times were charged with all the books lost or missing from the library during their terms of service. Dr. James Hutchinson and others were thus charged with books lost or mislaid. Dr. Joseph Hartshorne is mentioned as a delinquent for four octavo volumes; Dr. C. S. Hopkins, besides being charged with a very large number of lost books, had charged against him one hundred and five tracts. The care of the patients was intrusted to students who lived in the house; they also acted as apothecaries, although now and then professional apothecaries were engaged for a salary. In 1770, William Smith, an apothecary, was imported from England. He received one hundred pounds a year, "with good and sufficient meat, drink, washing, and lodging, such as is necessary, usual, and customary for one in his station." His bond was very carefully executed and signed in London. When apprentice students were introduced, this plan was abandoned, so that from 1787 to 1821 the duties of apothecary were performed by the medical apprentices.

In 1820 the present system of resident physicians was adopted. In the admission books of early times we find patients admitted with some strange diagnoses,—"eruptions all over," "a very bad sore leg," "a rotten leg," "a bad eye," and "a very bad sore head;" and one had "a bad cough and short breath," and another "a decay." The apprentices (some of the early ones also acted as stewards) were indentured to the hospital by a bond which in its provisions seems rather iron-clad. Fortunate indeed have been some of the residents of later times, that no such security is demanded.

Jacob Ehrenzeller received the first appointment as medical apprentice, in 1773. He was indentured to serve five years and three months. He had leave to attend lectures out of the hospital during the last two years of his apprenticeship, and enjoyed the privilege of the hospital lectures free of expense. There were three appren-

tices. The oldest became a graduate before the expiration of his indentures. John Saxton, the steward, in 1774 applied to apprentice his son, aged fourteen years, for seven years.

The managers made some very strict rules; for instance, they resolved that

"The apprentices shall on no occasion be absent from the house without leave expressly obtained from the sitting managers; they are to look for no indulgence by leave to attend parties of pleasure or places of amusement, nor to be abroad in the evening; nor will it be considered for their benefit to receive visits at home,—none of these things making any part of the views of careful parents or friends in placing them, nor of the managers in securing them as apprentices."

In 1814, John Rhea Barton, who was subsequently elected and served thirteen years as an attending surgeon, was indentured to the hospital for five years; his bond reads:

"During which time the said apprentice his said masters faithfully shall serve, their secrets keep, and their lawful commands every way obey; he shall do no damage to his said masters, nor see it done by others, without letting his said masters have notice thereof; he shall not waste the goods of his said masters, nor lend them unlawfully to any; he shall not commit fornication nor contract matrimony within the said term; he shall not play at cards, dice, or any other unlawful game, whereby his said masters may have damage. With his own goods, or the goods of others, without license from his said masters, he shall neither buy nor sell; he shall not absent himself day or night from his masters' service without their leave, nor haunt ale-houses, taverns, or play-houses, but in all things behave himself as a faithful apprentice ought to during the said term."*

The said John Rhea Barton further covenanted to "provide himself with a feather-bed for his own use, which bed he is to leave in the hospital when he leaves it." He also agreed to deliver up the books in the medical library and articles in the museum as they were delivered to him, etc.

For all this it was covenanted

"That the said masters shall use the utmost of their endeavors to teach, or to cause to be taught or instructed, the said apprentice in the trade or mystery of an apothecary, and provide and procure for him sufficient meat and drink, room to lodge in, and washing fit for an apprentice."

That the managers of this hospital recognized the ability and faithfulness of the medical apprentices is well shown in the parting with Dr. Joseph Hartshorne, in 1806, who resigned one month prior to the expiration of the term for which he was elected as an apprentice, in order to take a voyage to India. The minute states, and I quote only a small part, "that his conduct has been uniformly such as to merit the entire approbation of the managers and patients, and to secure him their esteem and highest respect. In the practical duties of his profession he has displayed, under the inspection and advice of six of the most eminent physicians and surgeons of Philadelphia, a skill seldom to be met with in a practitioner of his years, and the uncommon success with which his practice was marked left us no cause either to regret or to diminish our confidence in him."

Dr. Hartshorne became one of the most distinguished physicians that Philadelphia has produced: he died in 1850. One who knew him well said of him, "He was the most scrupulously truthful man I ever knew." The estimate the Board of Managers placed upon him was thus fully realized.

The first matron, elected in 1751, served nine years, during which period she also acted as steward. She received twenty pounds a year, and firewood, provisions, and accommodations for herself and two children. The stewards, the first having been appointed in 1758, seem to have acted in various capacities.

The bill of John Story, in 1779, charges for services as steward, physician, resident apothecary, and surgeon, for three years and seven months; and it seems, from one of the items, that his daughter had been for years the hospital cook.

Curiously enough, two burials have been allowed in the garden of the hospital. The first was that of Charles Nicholes, in 1808; the other was the wife of Stephen Girard, in 1815.

The grave of the former is directly opposite the present entrance; that of Mrs. Girard is a few feet to the west. The north wall of the present clinic-room rests upon these graves, so that the marble tablet which marked the grave of Nicholes, in

* This form of indenture appears to have been in common use during the early part of this century in Great Britain. (See *Philadelphia Medical Times*, vol. xv. p. 336.)

1868, was necessarily removed when the amphitheatre was erected. Charles Nicholes, in his will, requested that his body be buried within the limits of the yard, and left the hospital five thousand dollars. He directed his grave to be enclosed by a palisade, with a monument and a suitable inscription, and one thousand dollars was bequeathed for this purpose. To his physician and executor, Dr. Rush, he left one hundred dollars to write the inscription. The hospital has since continued to receive the benefit of this legacy, which the managers, in their minutes, then stated was "the largest ever bequeathed to the hospital by an individual." The grave of this benefactor of the hospital is now unmarked, and his tombstone lies neglected, broken and defaced, far from his remains.

This temporary omission to fulfil such a trust will undoubtedly soon be rectified. Dr. Rush stated that Nicholes, who was born on the island of Jersey in 1759, came to this country when very young. By strict integrity in mercantile business he accumulated in different parts of Europe and the United States about twelve thousand dollars, all of which he bequeathed in public charities. He informed Dr. Rush that no one living had any claim upon his duty or affection. He died December 31, 1807.

Stephen Girard's wife, Mary, was admitted for the first and only time as an insane patient, August 31, 1790, and died here September 13, 1815. In the month of January, four months after her admission, the sitting managers reported to the board their apprehensions that she was pregnant, and they called on Girard to take her home; but she was retained at his special request, and on March 3, 1791, was delivered of a female child, by Drs. Hutchinson and Gardener, just six months and three days after her admission into the hospital.*

I have thus given you some of the incidents connected with the early history of this institution. Many of these are new; they have all an interest. Some of these I have obtained in the discovery of ancient papers of the hospital which recently I made, others have been taken from the hospital records, and others were found for me by Mr. Malin, our friend of many years, around whom cluster so many happy associations. I know that I express the earnest hope of all present in saying, may he long be spared, to share with us the pleasures of our annual meetings.

I could not bring these remarks to a close in a more fitting way than by passing in review the many contributions which the medical officers of the hospital have rendered to science, and the service it has thereby been enabled to render medical education in this country, directly and indirectly, in its long and honorable career. During this long period of usefulness it has been utilized for the benefit of medical science, not only by training its medical apprentices and students and the thousands of students and physicians who have annually crowded its amphitheatre, but it has also been made to contribute very largely to the literature of medicine of the day.

The medical officers have been usually men of large attainments, and have frequently contributed to the medical press interesting reports, essays, monographs, and systematic works, and have originated, while in actual service of the hospital, not a few novel methods of treatment, which have since become the general property of the profession. However, as I understand that these will be considered in the paper to be read by our chairman, it will not be necessary for me to refer to them in detail.

In bringing these remarks to a close, allow me to express my gratification at seeing so large an attendance here this evening, many having come from a distance. May this be but an earnest of the future prosperity of the association which we have this evening so auspiciously inaugurated!

* This, the only child of Stephen and Mary Girard, died August 29, 1791.

ORIGINAL COMMUNICATIONS.

REMARKS ON THE CLIMATE-TREATMENT OF PULMONARY CONSUMPTION.

Read before the Philadelphia County Medical Society, December 9, 1885,

BY J. C. WILSON, M.D.,

Physician to the Philadelphia Hospital and to the Hospital of the Jefferson College.

THE subject of the climate-treatment of consumption is, Mr. President, much too comprehensive to be adequately discussed in a single evening. When we consider that this subject has a very extensive literature of its own; when we recall

in this department of therapeutics the labors of Weber, Bennet, Sparks, Jourdanet, Beneke, and others abroad, and of Flint, Loomis, Dennison, Geddings, Tyndale, and Kenworthy, in this country; and when we glance at the difficulties of the subject itself, which embraces many unsolved problems, it is apparent that in a brief paper salient points only can be taken up, and that even these must be treated in a manner suggestive rather than exhaustive. If, in the course of my remarks, particular localities are mentioned, it will be rather by way of illustration than with any view of attempting to describe them or their merits.

To the practitioner, the main questions that suggest themselves are two. First, what individuals are likely to receive benefit from this treatment? and, second, to what particular localities are such individuals to be sent?

I regard the answer to the first of these questions as fraught with the most serious responsibility. It is not enough to determine that any particular patient is likely to be benefited by a change of climate, but the decision must in every case be influenced by numerous collateral considerations of importance. These relate to the occupation of the patient, his family ties, means of support, habits, mental peculiarities, and the like. As a matter of fact, the proportion of patients who are able to avail themselves of the treatment by climate is necessarily a small one, the expense being such that few can afford it. For the majority, this treatment means, in a word, the abandonment of home and of family and business interests, which are scarcely less important than health itself, for a search after health which proves too often a vain one. These sacrifices are the more difficult to make, for the reason that, to secure the desired end, they must in most cases be made at a time when the patient is still able to pursue his ordinary avocations and is indisposed to regard himself as an invalid. For the poor, then, or those who have others dependent upon them, the climate-treatment of consumption is too often unavailable. More fortunate are they whose means and personal independence permit them to undertake those changes of residence which offer the best promises for restoration to health, and at a time when these promises are likely to be fulfilled. Too often among this group are those in whom the character of the disease and the family history may give rise to fair doubts as to the expediency of an exile from home and friends as a means of treatment. I refer particularly to individuals whose family history shows a strong predisposition to pulmonary consumption of rapid form and developing in early life. The risks of sending such individuals away from home, especially if they are obliged to go alone, are such as to make a careful physician hesitate, even though the evidences of phthisis may be as yet slight.

The question as to the time at which patients are to be sent away is of cardinal importance. Those will derive most benefit from change of climate who make it at an early period in the course of the disease. On the other hand, there is little doubt that lives are often prolonged and made comfortable by change of climate after the disease has made very considerable progress. Less regard is to be paid, in this connection, to the stage of the disease as indicated by the physical signs than to its previous course and rate of progress, and to general constitutional conditions relating to strength, nutrition, appetite, digestion, the presence or absence of fever, and the like. The phthisis of young persons of a bad family history, that form characterized by sudden onset, rapid development, and fever from the beginning, is little likely to be arrested by climatic change. To such persons, who are usually unwilling to recognize the gravity of their illness, travel and hotel life are attended with extreme hardship. They constitute a large proportion of those to whom the climate-treatment of consumption does more harm than good. Patients likely to derive the greatest benefit from change of climate belong to one or the other of the following groups of cases: first, those with a bad family history, in whom the climate-treatment is adopted early; second, those in whom the disease is of slow development; third, those in whom the physical signs of pulmonary lesions are associated with slight or only moderate constitutional disturbance; fourth, cases of fibroid phthisis which are the result of long-continued recurrent or chronic bronchitis, particularly those forms which develop in middle life and are of slow progress, and in which the symptoms are aggravated by vicissitudes

of the weather. Many of the patients forming these groups can scarcely be classed as invalids, and are always unwilling to regard themselves as such. Hence they are with difficulty induced to make those personal sacrifices which the climate-treatment demands. He will reap most benefit from change of climate who still has the strength and health to live in the open air, to amuse himself, and to be occupied in mind and body; he the least who finds himself an invalid, feeble, wretched, suffering, away from home and friends, too weak for occupation, too wretched for amusement, a stranger in a strange land. We must not overlook the facts, also, that the exile must in many cases be a long one, that the cure is often found to have been only apparent when the patient returns to his city-life and his old occupation, and that the *poitrinaire*, having found a climate that suits him, does wisely if he takes up his permanent residence in it.

When we come to the consideration of the second main question, — namely, "Where are we to send our individual patient?"—we encounter difficulties still more important. It is no easy task to determine beforehand with precision what particular locality will most benefit a given patient. Whilst the difference in this respect between mountain and maritime climates is probably less than has been thought, it by no means follows that the choice is a matter of indifference. On the contrary, it has been found by experience that, from the therapeutic standpoint, climates useful to certain individuals are disastrous to others. We must here consider also many collateral subjects which relate to the physical and mental well-being of our patient: the character of the life, society, comfort of living, food, amusement, too great congregation of other invalids, etc. Nor must we overlook the necessity for skilled medical advice in case of emergency, its desirability at all times. A multitude of matters demand careful consideration in the selection of the locality. Many of these are difficult to ascertain; the sources of information are not always satisfactory; yet more knowledge concerning them than is sometimes possessed by the physician would save much unnecessary expense and trouble and loss of precious time on the part of the patient. One of the objects of the recently-organized American Climatological Association is the accumulation of reliable data of all kinds in reference to the health-resorts of this and other countries.

The reputation of particular localities in the treatment of phthisis must have been originally the result of observation, and must have depended upon the recognition of two facts: first, the slight prevalence and low death-rate from phthisis in a given locality; and, secondly, the improved health of individuals suffering from the disease after coming to it. The reason why the climate of particular localities is beneficial is only now being scientifically worked out with great labor. It has been suggested that the immunity from phthisis in situations which are sparsely settled may be due not so much to climatic influences as to the fact that these situations are free from influences which contribute to the prevalence of the disease in cities and other thickly-settled places, such as in-door occupation, overcrowded dwellings, etc.

Various attempts have been made to classify climate, with more or less want of success, for, as Yeo suggests, in most instances what has been gained in precision has been lost in accuracy. This observer regards as well grounded the fundamental division into (*a*) sea or insular climates, (*b*) inland or continental climates. Other divisions have been suggested, as into (*a*) dry and (*b*) humid; or, again, into (*a*) the climate of plains and (*b*) the climate of altitudes; or, again, into torrid, warm, temperate, cold, or polar climates. Dennison, of Denver, has suggested a classification of climates based upon an equitable combination of the humidity statistics of the atmosphere, his object being to rate the sections according to their records in such a way as to indicate numerically the relation in respect to cloudiness, relative humidity, and absolute humidity. Finally, Germain Sée divides climates into three categories, viz.: (1) warm maritime climates; (2) climates of altitudes, which are necessarily cold; and (3) climates of low countries, not maritime.

Broad generalizations in regard to the climate of particular localities are, however, apt to be misleading. The climate of a place is in reality the sum of influences relating to its temperature, altitude, soil, drainage, vegetation, cultivation, popula-

tion, prevailing winds, and its nearness to or distance from large bodies of water on the one hand or abrupt mountain-ranges on the other. Variations in any one of these factors may occasion important modification. We all understand the value of sunshine in our rooms; but in most winter-stations, whether in high altitudes or upon the sea-coast, the differences between rooms with a northern and those with a southern exposure are such that the former are practically uninhabitable, and no traveller in Italian cities has failed to be impressed with what might be termed the difference in climate between the sunny and the shady side of the street. A cardinal error, therefore, is that of regarding climate solely from the stand-point of the meteorological data of a place or region.

The general properties of maritime climates may be briefly summed up as follows: (*a*) humidity, uniformity of temperature between winter and summer, as well as between day and night, with sudden changes determined by local influences; (*b*) high barometric pressure, with marked though regular oscillations; (*c*) an alternation of land and sea breezes; (*d*) abundant sunlight; (*e*) abundance of ozone, the excess of which is due to the physico-chemical action of sunlight, evaporation, and the motion of the air. It is possible that the presence of ozone in large amounts has much to do with the favorable influence of sea air upon nutrition; (*f*) comparative or absolute freedom from organic and inorganic impurities in the atmosphere, except malaria, which is occasionally present. Of minor importance is the presence of saline particles suspended in the air, such as small amounts of iodine and bromine in combination.

Beneke discovered in 1872, as the result of experimental investigations into the action of sea air conducted on the isle of Norderney in the North Sea, and of mountain air at a point near Interlaken, that heat is lost from the self-same apparatus more slowly on the tops of mountains than on the shores of the North Sea, and this notwithstanding the fact that the mountain-temperature was almost constantly lower, a circumstance which would have led us to expect a more rapid loss. He also observed at the sea-shore increased tissue-change, manifesting itself by an increased elimination of urea and sulphuric acid, diminution of uric and phosphoric acid, and increase of body-weight.

Beneke observed, in addition to these facts, in the sea-climate, slight slowing of the respiration and of the pulse, which he ascribed to the increased barometric pressure and to the humidity. The favorable results of warm maritime climates in the treatment of phthisis appear to be due in part to the increased barometric pressure favoring the entrance of larger amounts of air into the lungs; to the frequent and often rhythmical variations in the barometric pressure, which directly favor the action of the organs of circulation and respiration, and effect indirectly an unquestionably favorable influence upon organic life. They are partly due also to the large amounts of ozone present and to the absence of organic and inorganic impurities in the atmosphere. Certain observers ascribe the beneficial influence of sea-climate wholly to conditions which render it unfavorable to the support and development of the tubercle-bacillus.

This category includes the climates of the sea, small islands, the coast-line, and peninsulas. Among maritime climates in this country suitable for winter-stations for those suffering from consumption are those of the peninsula of Florida and of Southern California. Important as they are for the climate-treatment of other conditions, Atlantic City, Cape May, and Old Point Comfort can hardly be regarded as adapted to the climate-treatment of phthisis; but this does not apply with equal force to all Northern sea-side resorts, for Newport possesses peculiarities which unquestionably exert a favorable influence over the course of certain chronic pulmonary disorders.

It is very easy to recognize what is meant by a sea-climate. When, however, we come to speak of mountain-climates, we are at once met with a difficulty which must be overcome by a purely conventional arrangement. This difficulty relates to the altitude. The limits of high-altitude climates extend from about three thousand feet to seven thousand feet. Below this belt the climate could hardly be regarded as a climate of high altitude for therapeutic purposes; above it, except for occasional purposes and short periods of residence, the climate is undesirable.

The general properties of high-altitude climate are (*a*) its lower temperature.

The medium loss of temperature is 1.8° F. for every five hundred and twenty feet of elevation during summer, and every nine hundred and ten feet during winter. It follows from this that the summits of mountains are relatively much warmer in winter than in summer. Actually, however, the temperature is not only lower, but there are greater differences between day and night than at the sea-shore. (*b*) Diminished humidity, although in this respect there are great variations, which depend in part upon the configuration of the land (acting by modifying condensation), and in part upon the presence or absence of vegetation; (*c*) greatly-diminished barometric pressure in proportion to the height, without the rhythmical variations of sea-climates; (*d*) abundant sunlight; (*e*) excess of ozone; (*f*) comparative freedom from organic and other impurities.

At the beginning of a sojourn in a high altitude the heart's action is increased in energy and frequency; this increase, however, is of short duration. The respirations are also at first more frequent and deeper, and the thorax becomes slightly enlarged; but these changes are likewise transient. The amount of oxygen inspired is said by Jourdanet to be diminished. The elimination of water and carbon dioxide by the lungs is increased; tissue-change is also increased; the appetite is augmented, and nutrition is favorably influenced. The climate of high altitudes may be said to be somewhat stimulating to most of the functions of life.

The most important regions of high altitude in this continent adapted to the treatment of pulmonary phthisis are to be found on the eastern slopes of the Rocky Mountains, the plateau of New Mexico, and the little known grand plateau of Mexico.

Germain Sée, in summing up the characters constituting the most important climatic factors of mountain and sea air, points out that they possess in common great purity, abundant light, and excess of ozone; and that, on the one hand, the presence of traces of bromine and iodine renders sea-air antiseptic, and, on the other hand, the cold of high altitudes has a similar effect. The most striking difference between them relates to the barometric pressure. The apparent contradiction that the increased pressure of the sea-level and the diminished pressure of high altitudes exert a like favorable influence upon the course of phthisis he seeks to explain by the fact that the air in both these localities is unfavorable to the existence of the bacillus tuberculosis. It seems to me more probable that the apparent contradiction is simply an illustration of the adaptability of the human organism within limits to varying conditions.

Certain localities, neither maritime nor mountainous, have enjoyed a great reputation in the climate-treatment of phthisis. Among these are Pau in Europe, the banks of the Nile in Egypt, and in this country the Adirondack region, Lakewood and other points in New Jersey, certain regions in western South Carolina and Georgia, and some parts of the interior of the peninsula of Florida. Regions of this kind, possessing a porous sandy soil and well wooded, especially when with pine, are of unquestionable advantage to consumptives. The temperature of such localities is more nearly uniform than that of high altitudes or sea-coasts as regards day and night; the relative humidity is considerable; there is protection against winds; ozone is usually abundant; and if the woods interfere with an abundance of sunlight, the difficulty is one that is easily overcome in the neighborhood of houses and settlements. It is probable that the climates just described are more desirable for patients having a marked hemorrhagic tendency than either maritime or high-altitude climates. Furthermore, these localities are, in this country at least, much more accessible than the high altitude climates, and are, therefore, better adapted to cases of uncertain prognosis.

With reference to maritime climates, hemorrhagic cases and cases characterized by a tendency to fever should not be sent to the immediate neighborhood of the sea-shore. Individuals prone to easily-excited febrile movement do much better some distance inland. The danger of hæmoptysis in high altitudes has, I believe, been overestimated.

In conclusion, it has seemed to me desirable to avoid dwelling upon the advantages and drawbacks of particular localities, and I desire to call attention to the difficulty in obtaining accurate information in regard to the results of treatment, —difficulties that arise in part from the complex nature of local climate itself, and

in part from the uncertainty of the results, as far as obtainable by existing methods.

HYOSCINE HYDROBROMATE.

Read before the Neurological Society of Philadelphia, October 26, 1885,

BY HENRY M. WETHERILL, JR., M.D.

WE do not, as yet, know accurately the history of the discovery and introduction of this most important and valuable therapeutic agent; but certain it is that Landenberg, of Germany, was the discoverer of hyoscine and the first to investigate its properties. His observations were seconded by those of Edelfsen, Gnauck, Emmert, and others on the Continent. The English current medical literature has, I think, not made mention of it. To Dr. Horatio C. Wood belongs the credit of being one of the first to investigate its action in this country, as seen in his admirable monograph, published a few months since.

It is said that hyoscine is prepared by a rather complicated process from the alkaloid hyoscyamine, by treating the latter with baryta-water. The pure alkaloid hyoscine is so volatile and perishable that it is never available as a therapeutic agent unless combined with acids, which form with it salts of fair stability. Those at present found in the drug-market are the hydriodate, hydrobromate, muriate, and, I think, the sulphate. My experience has been wholly with the hydrobromate, and it is this salt alone of which this paper treats. The most reliable is that produced by E. Merck, Darmstadt, whose three accredited agents in New York are Lehn & Fink, Schieffelin & Co., and Eimer & Amend. It can be obtained of the leading pharmacists of this city. In its gross physical appearance it resembles small crystalline masses and granules of potassium bromide. It is light in relative weight, opaque white (but not purely so, slightly inclining to be yellowish), rather deliquescent when exposed to the air. Seen under the microscope, it was very evident that its crystallization had been facilitated by stirring, as much of it was in very irregular granular masses; but when allowed to evaporate spontaneously from its aqueous solution, it showed under the microscope handsome quadrahedral crystals springing from a granular base. These were entirely free from extraneous matters, transparent, and highly refractive.

The literature of hyoscine is rather meagre in America. Brief notices of it are to be found in the more recent works on therapeutics and materia medica. The other works devoted to this subject are Dr. Wood's monograph, the paper by Dr. Judson B. Andrews found in the *American Journal of Insanity* for October, 1885, a paper emanating from the Hudson River Hospital for Insane in the *New York Medical Record*, 1885, and some papers from the pen of Prof. John M. Maisch in the *Philadelphia Journal of Pharmacy* for November, 1885.

Hyoscine hydrobromate is freely soluble in cold distilled water; but it will be found desirable to add to this menstruum ten per cent. of alcohol as a preservative. The following I have found to be a convenient formula:

℞ Hyoscinæ hydrobromat., gr. j;
Aquæ destillat., f℥ix;
Alcoholis, f℥j. M.

In every ten minims of this solution there is $\frac{1}{60}$ of a grain of the hyoscine hydrobromate. In prescribing the compounds of hyoscine, care should be used in writing the name of the salt in full and plainly, so as not to mislead the pharmacist with the impression that hyoscyamine has been ordered, and *vice versa*, as the hyoscine salts are far more powerful than are those of its sister alkaloid.

Now, thus having described the substance at some length, what have we found to be its exact physiological effects, and what do we find to be its true place in therapeutics after a very careful and painstaking study of its action, which has extended over a period of six months, upon the patients under our care in the Pennsylvania Hospital for the Insane?

Before answering this question, let me recount the effect produced upon myself by a very moderate dose taken by the mouth. I was in health at the time. Dose, $\frac{1}{120}$ of a grain. Before administration, pupils normal, equal; pulse, 88, good; respiration, 20 per minute; skin normal; temperature, 98° F. Within forty-five minutes the pupils were evenly and moderately dilated, the voice was hoarse, face suffused, conjunctivæ injected, temperature raised to 99.5° F., respiration full, slowed to 16 per minute,

pulse slowed to 64, very full, considerable general relaxation of muscles, decided general sweat, impaired co-ordination, and a sense of fulness in the head and of wretchedness. I managed somehow to get to bed and at once fell asleep, and so continued for nine hours. Awoke much refreshed, no ill effects, everything normal but the pupils, which were yet slightly dilated, but which regained normal conditions within two hours.

Now, in regard to our results as obtained by its use in the hospital. I have no hesitation in saying that as a hypnotic and sedative it has proved most valuable in our hands. As a hypnotic, the usual range of dose is from $\frac{1}{120}$ to $\frac{1}{90}$ of a grain given at bedtime, preferably by the mouth; very frequently a less dose than gr. $\frac{1}{120}$ will be sufficient; gr. $\frac{1}{200}$ has often acted better in insomnia than has a larger quantity. It is very seldom necessary to repeat the dose; and another very decided advantage possessed by hyoscine over hyoscyamine is that small doses can be continued for a long time without increase; whereas the patient soon tolerates small and then moderate quantities of hyoscyamine, and finally resists even very large doses of it. We have given hyoscine a thorough trial in the insomnia occurring in the course of acute delirious mania, and with marked success, having succeeded, when all the usual modes of treatment had proved inadequate, in securing for the patient from six to ten hours of quiet sleep nightly for the past nine weeks, with but four or five exceptions; but one dose in every twenty-four hours, at bedtime, the amount ranging from gr. $\frac{1}{120}$ to $\frac{1}{70}$. The insomnia in these cases is one of their chief elements of danger. If it is possible to give such a case a fair amount of sleep and of nourishment in a concentrated form, the probability of a favorable issue might be entertained. In the insomnia of agitated melancholia, of the morphia habit, of alcoholism, of acute mania, of neurasthenia, of chronic mental disorder, with habitual wakefulness and motor activity, and in those confirmed cases of insomnia from unascertained cause which usually prove so obnoxious to treatment, hyoscine has been found to answer a very good purpose. It does not invariably succeed; but the failures have been very exceptional. In many instances the chronic insomnious habit has been broken so as to permit of the withdrawal of the hypnotic. It is a severe test of the value of any hypnotic to administer it in daytime, and the drug under consideration has been found to act very well even under this condition. It seems scarcely necessary to refer to the unsatisfactory and often disappointing action of the hypnotics which are now in general use, and it would seem as though this remedy is the one for which rational therapeutists have waited for so long a time.

Now, as to its usefulness as a general sedative, we have had results which justify the assertion that it is the very best means at present at our disposal for calming the motor excitement of acute and chronic mental disorders in their talkative, active, noisy, destructive, or violent phases. In this class of cases the range of doses may sometimes have to be greater than in the treatment of insomnia: from gr. $\frac{1}{120}$ to gr. $\frac{1}{50}$. I have seldom been obliged to give so much as gr. $\frac{1}{50}$, and have rarely had to give more than one dose in twenty-four hours. As an occasional exception, a patient has been found whose excitement has successfully resisted a full dose; but it must be remembered that some cases of chronic mental excitement have been dosed with varying success through a period of years, until a peculiar condition of resistance to and toleration of remedies of this class has become established. Where a large number of excited patients are congregated, even though they may be classified with care, there are a few who seem to be the cause of most of the general disorder and confusion: reduce these few to a condition of comparative quiet, and the larger but less aggressive element remains tranquil. Following out this theory in the administration of hyoscine, we have had the satisfaction of seeing wards for excited patients quite transformed in character for the better; nor can this be fairly termed "medical restraint."

I have tabulated carefully our study of the physiological action of this remedy as a hypnotic and as a sedative, and have also tabulated our experience with hyoscyamine as a hypnotic. We had found the latter so decidedly inferior to hyoscine as a sedative that it was not deemed necessary to tabulate these results; but it must not be inferred from this that hyos-

cyamine is inert; it is a remedy of no mean value, and only second in activity to its sister alkaloid.

The tabulated statements to which reference has been made will appear in the forthcoming Report of the Committee on Lunacy of the Pennsylvania State Board of Charities for 1885.

Physiological Effects.—The physiological effect of a full dose of hyoscine, say gr. $\frac{1}{60}$, is manifested within twenty minutes. These are—brief, transitory bewilderment; marked interference with co-ordination; widely-dilated pupils; slow, regular, very full pulse; dryness of the throat; relaxation of the vocal cords; very slow, full respirations, sometimes becoming Cheyne-Stokes; marked suffusion of the face and of the general surface of the body; a slight rise in temperature; and free diaphoresis, which does not seem to restore normal temperature. There is general muscular relaxation and a sense of wretchedness. Sleep usually follows, which continues from one to five hours, if the dose is given in daytime and the patient is not put to bed. This amount, administered at night, would be followed by sleep lasting for eight or ten hours. The mydriatic effect is rather transient, but usually persists through an entire day. The pulse is slowed about twenty beats per minute, and this effect gradually wears away during eight or ten hours, and is often followed by a very variable period of pulse-acceleration, which seems to be simply a reactionary hastening of the pulse to restore the disturbed balance of the circulation. The normal rate of respiration is gradually restored through a period ranging from three to five hours.

The rise in temperature is not an invariable result, and is frequently small,—seldom exceeding one and a half degrees,—and the balance of temperature is usually restored within two or three hours. Dryness of the throat often persists through an entire day. Suffusion of the surface of the body is usually transitory. In moderate and in small doses the effect is, of course, proportionate to the amount employed; but the same general symptoms are present, and the patient is quieted accordingly. Interference with the appetite is sometimes observed. It does not seem to act upon the bowels nor upon the kidneys.

Hyoscine is not always well borne; occasionally the following symptoms have followed the use of a moderate dose: nausea, vomiting, anorexia, dysuria, syncope, with small, rapid, irregular pulse, and with symptoms of partial paralysis of the pneumogastrics. This untoward condition occurred in a case of epileptic mania, in one of paretic dementia, in one of chronic dementia with excitement, and in one of acute hysterical mania. All of my personal experience of the action of hyoscine has been among females, and they are, I think, more susceptible to its action than are males. This is generally true of many drugs. Hyoscine is a spinal sedative of considerable activity. It had a decided influence over the spasms of a case of tetanus,—a powerful man, whose life it certainly prolonged for some hours, and who died, not from convulsions, but from high temperature: this was, I think, 108° F. before death; but post mortem it rose to 116° F. This case was not mine; but I know that the observations were accurately taken with a corrected thermometer.

Is it best to give the remedy hypodermically or by the mouth? It acts almost immediately and in rather less dose by the former method; yet we have preferred usually to give it by the mouth, as it acts very promptly when taken into the stomach, even in very small doses, and this method offers no shock to an excited or timorous patient.

Among the physiological effects of hyoscine, one or two observers claim to have frequently noticed a primary acceleration of the pulse-rate previous to its becoming slow and full. This I have not found to be the case save in two instances, and even in these two cases the effect was not invariable. There is a source of possible error to be here taken into consideration,—that the mere act of feeling the pulse or even addressing some persons causes a marked acceleration of the pulse, which may persist for some time should the patient be excited, timorous, apprehensive, or nervous.

From three observers of the action of hyoscine in another State comes the report that their anticipations of the good effects of the drug had not been realized after fair trial of an article which they thought was reliable; but there is some reasonable ground for doubt that the substance employed emanated from Merck's

laboratory. The evidence that it is a hypnotic and sedative of great value to the profession is rapidly accumulating. We have thus far found the different samples of Merck's hyoscine hydrobromate to be uniform in effect and in external characteristics, and are much pleased with its action. It has been in daily use and under close observation in our hospital practice, and we prescribe it with confidence in its activity. It is preferable to the other sedatives and hypnotics, as it is more certain and uniform in effect, convenient in administration, and free from injurious secondary effects.

TRANSLATIONS.

APHONIA DUE TO NASAL ABNORMALITIES.—In the *Revue Mensuelle de Laryngologie, d' Otologie et de Rhinologie*, No. 12, appear several contributions reporting cases of aphonia due to various abnormalities of the upper air-passages, from the proceedings of the Société Française d'Otologie et de Laryngologie. Dr. J. Baratoux reports a very interesting and curious case of a lady suffering with loss of voice, apparently due to reflex irritation from hypertrophy, particularly of the middle turbinated bone. That the loss of voice was attributable solely to this cause was an inference from the sudden recovery of the voice upon the removal of the hypertrophy with the galvanic loop. The reflex irritation in such cases is attributed to the swelling over the turbinated bone or a deviated septum, by which the sensitive area on the former is brought into contact with the latter. Dr. Breboin communicates the history of a man, 60 years of age, where aphonia was cured by the removal of a number of gelatinoid polypi of the nose; also a case of a young girl, 22 years old, in whom removal of a median hypertrophy restored the voice, which had been completely lost. Spasmodic aphonia and spasm of the larynx, due to a similar cause, is illustrated by three cases contributed by Dr. Hering. [The possibility of confounding such cases with hysterical and neurasthenic aphonia makes them of special interest both in point of diagnosis and treatment.—ED.]

CHYLOUS EFFUSION INTO THE PERITONEAL CAVITY.—An interesting case of chylous abdominal effusion in an infant is reported by Dr. M. Letulle, in which the chemical examination of the fluid obtained by aspiration was made with unusual care. The child was thirty-two months old, and suffered with an obscure hepatic affection, chronic peritonitis, and cardiac disorder (congenital?), and orthopnœa due to double hydrothorax. Tapping brought away a large quantity of ascitic fluid resembling urine. A month later another large quantity was removed, which was thicker and rather milky. In a third and fourth aspiration a chylous fluid was obtained, which contained emulsified fat. A fifth paracentesis has not been required, and the child was steadily improving under treatment when the paper was published.

A *résumé* of cases reported by different observers, twelve in number, is appended to this report, with a view to determine the pathological import of chylous effusion into the peritoneal cavity. Without going into the further details of this interesting report, we give the conclusions of the author:

1. Chylous effusion of the abdominal cavity, considered chemically, is a product which should be placed between serous and sero-purulent ascitic effusions.

2. As this liquid always is accompanied by peritoneal morbid conditions (cancerous, tuberculous, or due to new formations) more or less old, it is logical to consider it as a residual lesion. It is, therefore, a rare (or rarely recognized) form of peritoneal effusion undergoing granular fatty degeneration.

3. Until more light is obtained upon this subject, the great majority, if not the totality, of cases of ascites called chylous should be referred to the class of chronic peritonitis.—*Revue de Médecine*, No. 11.

CALOMEL INJECTIONS IN SYPHILIS.—Professor Neisser, of Breslau, uses the following formula in the treatment of syphilis by hypodermic injection:

℞ Hydrargyri chlorid. mitis,
Sodii chloridi, āā 5.
Aquæ destillatæ, 50.—M.

To this mucilage of gum arabic, 2.5 parts, might be added. Injections of this containing doses of calomel from 0.4 to 0.6, or even 0.1 Gr., may be made once a week: generally the back is preferred. Abscesses are rare.—*Deutsche Medizinal Zeitung*, November 30.

EDITORIAL.

POISONOUS SEA-FOOD.

THE noxious effects in certain persons of fish as an article of diet, and particularly of shell-fish, is a matter of familiar occurrence, usually accounted for on the ground of idiosyncrasy. Individuals who are unable to eat fish may be arranged in two groups,—first, those who experience unpleasant effects, which, while annoying, are not of a serious character, consisting merely in transient gastro-intestinal derangement, with or without urticaria; and, secondly, those who suffer from acute, often alarming, symptoms referable to the digestive organs, and accompanied by nervous oppression, feeble circulation, and collapse. Upon a different principle of classification, Schreiber, of Königsberg, refers cases of fish-poisoning to two categories,—namely, those occasioned by the eating of fresh fish, and those by the eating of preserved fish,—and regards it as probable that the toxic principle in the second group of cases is a ptomaine. The grave symptoms occasionally observed in those who have eaten stale oysters and other shell-fish when more or less advanced in the state of decomposition are very probably due to this cause. Salkowski regards it as probable that the acute poisoning produced under certain circumstances by the consumption of fresh fish is due to the presence of an alkaloid; but to apply to such an alkaloid the term ptomaine would be to use this term in a much broader sense than hitherto. Up to the present time, those substances only have been designated ptomaines which have been developed through the agency of putrefactive changes in animal organic tissues. It is of interest in this connection to note (as stated by Parkes) that rotten fish are constantly used by the Burmese, Siamese, and Chinese as a sort of condiment, and without bad effects. Certain fishes in the Indian Ocean, which are used by the islanders as food during nine months of the year, become during the three remaining months poisonous, and even produce fatal effects! Here is a sort of periodical virulence, probably to be explained by some change in the food of the fishes during the period in question. Shell-fishes commonly considered edible appear to acquire in certain localities poisonous qualities. Among these is the ordinary sea-mussel (*Mytilus edulis*). Aurel Krause records the fact that in one of the first English expeditions to Alaska, in 1793, one individual died with symptoms of poisoning after eating mussels, and that others were extremely ill. The natives avoid these shell-fish at certain seasons on account of their poisonous properties, which, however, they are free from at other seasons of the year. The same author states that in 1799, in the neighborhood of Sitka, more than one hundred Aleutians lost their lives in the course of a few hours after having partaken of mussels discovered during a journey. Many other instances of fatal poisoning have occurred during the present century from the same cause. The last of these was made the subject of an interesting communication to the Berliner Medicinischen Gesellschaft, November 9, 1885, by Virchow. It occurred in Wilhelmshaven, under the following circumstances. Two vessels were dry-docked and cleaned. During this process a large quantity of sea-mussels were removed from the hulls (which, however, were not coppered) and piled upon the wharf. In the course of the day a number of the workmen and others who had eaten of these mussels fell ill. Of these, thirteen were men, of whom three died, five were women, and one was a child,—nineteen in all. The whole number of fatal cases was

four, of severe cases in which recovery took place ten, of light cases five. The symptoms in all the cases were the same. In the course of a short time or several hours, according to the quantity eaten, there was experienced a feeling of contraction in the neck, mouth, and lips, prickling and burning at first in the hands, later in the feet, dizziness without headache, and a curious feeling of lightness in the extremities. These phenomena were accompanied by an excitement analogous to that produced by alcohol, restlessness, and a sense of oppression. The pulse was hard, 80 to 90 per minute, the temperature normal, the pupils dilated and fixed. Speech was difficult and broken. Now followed a sense of weight in the limbs, stiffness in the muscles, and vertigo with continuous vomiting unattended by pain or diarrhœa. So violent were these symptoms that in one case death occurred in three-quarters of an hour, in a second, within three and a half hours, and in a third, in five hours after the eating of the mussels. The quantity which gave rise to serious symptoms did not exceed in some instances five or six mussels. Virchow's account of the post-mortem examination and of the experimental investigation of the toxic properties of the mussels themselves (in his communication to the *Berliner Klinische Wochenschrift* for November 20) is extremely interesting. Chickens and cats which ate the mussels in Wilhelmshaven were speedily taken sick and died. A large dog died in a very short time after having eaten some fragments of the mussels. A cat that simply licked the plate from which the mussels had been removed was taken violently sick, but recovered. Guinea-pigs and frogs quickly succumbed to the poison. The poisonous properties were contained not only in the cooked mussels themselves, but also in the broth and in an alcoholic extract which was prepared from them. The effects were obtained both through the stomach and by hypodermic injection. By the latter method the lethal effect was produced with great rapidity. In its powerful paralyzing properties this poison resembles curara, and merits further investigation not only from an economic but also from a medical point of view.

FEES FOR MEDICAL SERVICES.

AS the time approaches for closing the accounts of the year, the perennial question of fees may be appropriately considered. Strangely enough, with some this seems to be considered as rather a delicate one; but those who affect to despise the business aspect of professional life are either fatuous or hypocritical. The practice of the art of medicine offers an honorable means of earning a living, and hence it can be neither dishonorable nor undignified to devote proper attention to the honorarium, or "pecuniary acknowledgment," as the Code gracefully puts it. At the same time, judgment and tact are required to be exercised in order to prevent it from assuming an undue degree of importance in the intercourse with patients or the public. It is quite certain that physicians, as a rule, are too careless about their accounts, and are prone to affect indifference. The result is that the public is divided into two classes in this regard,—first, the class consisting of the select few who consider the physician's account as a debt of honor, having precedence over ordinary obligations; and, secondly, the larger class which regard it as a just claim, yet as one which they need be in no haste to discharge. Doctors' bills proverbially are the last to be paid. It is said that physicians have a larger proportion of bad debts than any other class of professional men, partly due to unbusiness-like habits and partly owing to the nature of their work, the prompt service required often admitting of no delay for discussing the terms of the contract.

A not inconsiderable amount of loss is therefore unavoidable, and their credits for services rendered to those unable to requite them must be entered in another place than their cash account.

With regard to the legal grounds for charge and the collection of claims due them, the laws are often explicit. It has been held in court that the right of a medical man to recover his charges for professional services does not depend upon his treatment having been successful, unless there is a special agreement to that effect. It depends for its legitimacy upon the skill, care, and attention bestowed, and not upon the outcome of the case: still, it must be shown that actual service has been rendered. The physician must be prepared to show that his work was properly done, if that be disputed, in order to prove that he is entitled to a reward. Where a surgeon has performed an operation which might have been useful, but which merely failed in the event, he is nevertheless entitled to charge; but, if it could not have been useful in any event, he will have no claim upon the patient.* Similarly, where a physician has made a patient undergo a course of treatment which plainly could be of no service, he cannot make it a subject of charge; but if he employed ordinary skill, and applied remedies fitted to the complaint and calculated to do good in general, he is entitled to his fees, although he may have failed in the particular instance, such failure being then attributable to some vice or peculiarity in the constitution of the patient for which the medical man is not responsible.

A physician or surgeon cannot claim reward for services required through his own negligence: thus, if he by communicating an infectious disease have rendered prolonged attendance necessary, he cannot recover for such additional service necessitated by his own want of care. This, according to Ordronaux, applies equally to puerperal fever when communicated by the attending physician. On the other hand, if a doctor's bill be not paid when presented, he is not limited by it to the amount of his claim if he can show that his services were of greater value. A physician called in for consultation or to perform an operation may recover his fees from the patient, notwithstanding that the attending practitioner summoned him for his own benefit and had arranged with the patient that he himself would pay. While a physician, in the absence of an express understanding, is only entitled to recover what is customary and reasonable for such service, yet it does not follow that all must rate their charges alike, for the value of their service differs greatly: where the attending physician intends to make an unusual charge, it would save trouble if his terms were expressly stated at the time of taking charge of the case.

In making out accounts, as well as in keeping books, it should be kept in mind that a visit *per se* does not afford ground for a charge, unless it can be shown that service also was rendered or a medical consultation held. A bill of items is required, when a claim comes before the courts, specifying the persons to whom service was actually rendered, the date of such attendance, and charges for consultations; although under ordinary circumstances, at present, an itemized bill is rarely made, except where a doubt has arisen or the amount of obligation is disputed.

* "Law and Medical Men." R. Vashon Rogers, Jr., Toronto, 1884.

A New Hypnotic Agent.—Urethane, an ether carbamic or carbamate of ethyl, is in the form of white crystals without smell, or slightly like saltpetre. It is soluble in water and in alcohol. It has been found that it has decided hypnotic effects in doses of one-half a gramme to one gramme. It is a good substitute for chloral and sodium bromide, and is without unpleasant secondary effects. It is a cerebral narcotic, and has been used to good advantage in delirium tremens and in mania. —*Pharmaceutical Record.*

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

AN eminent French judge has just publicly delivered an important opinion on the subject of professional secrets. According to French law, Article 378 of the Code, all physicians, surgeons, midwives, or druggists who may become possessed of secrets by the practice of their profession are forbidden to reveal them, except in certain cases laid down by the law, where they are obliged to denounce criminals. Infraction of the law involves a punishment by a fine of about one hundred dollars and imprisonment of from one to six months. Here two difficulties at once present themselves. A doctor might be called as a witness in a criminal case to testify to facts that have come to his knowledge in the exercise of his profession, but jurisprudence has established that he shall not testify in a way to reveal professional secrets, thus leaving it to his discretion what to say. The second difficulty is that a doctor called to attend a person who has attempted a crime or committed an act against life or property may in this case (according to an Article of the Code, No. 30, "all persons knowing of attempts on life or property are compelled to inform the authorities") find it his duty to report the crime if he knows of it when he is called, but the moment that he is in actual attendance he must be silent. Again, the doctor must not furnish any information as to the health of his patient, even in cases of proposed marriage. He can, however, delay a marriage, for instance, in the case of a patient who may be suffering from phthisis or any malady that may be acute and in danger of transmission. M. Bruno-Lacombe, the judge in question, stated substantially as above, and then said that if the prosecution turned against the doctor and sued him for damages the case is altered, and that he could then testify to all he knew. It is also claimed that the right to defence should be accorded to physicians if any serious accusation is brought against them in relation to any secrets which they may have acquired in practice. A doctor should give up any action he may have commenced for his fees (that is, non-payment of them) if the defence insists on knowing what was the character of the disease he has treated. When the marriage of any of his patients is decided upon, he should not reveal any disease they may have had, even with a view of preventing worse troubles after marriage. He must, however, tell a healthy nurse of the danger she incurs in nursing a child of his patient's who may have inherited syphilis, otherwise the nurse can sue him for damages. He can also denounce all attempts against female clients, except in case of abortion, where it would compromise the patient herself. The question was asked, "Ought a doctor, in order to save an innocent person, to denounce the criminal who may be under his care, and if he is aware of his guilt?" The answer to this is, "No." A case was cited of a trial that took place here lately, where a physician was called to see a newly-born child, and he saw that it was syphilitic. He recommended the mother to nurse her own child, and forbade the employment of a nurse; but they employed a healthy woman against the doctor's wish and without his knowledge, and the nurse got the disease. She sued the family, and the doctor was allowed to testify to the facts, and the woman got a verdict of substantial damages in her favor.

In regard to registration of births in France, Article 56 of the Code only imposes on physician and on midwives the obligation of declaring the fact of a birth at a certain house, but they are not compelled to give the name of the mother. As to death-certificates, the attending physician is at liberty to declare the real cause of death or refrain from doing so when this might injure the memory of the deceased or hurt the family.

Professor Peter is one of the most prominent men of the Paris Faculty of Medicine. In person he is quite small, short, and thin, wears a full, short beard, and still possesses what is so often wanting in younger savants, a scalp well covered with hair, which with his beard is now nearly white. His voice is of a thin, vibrant quality, but the notice of his lectures is always followed by a full amphitheatre, attracted by the doctor's great ability and his sharp attacks on some prominent scientists. Dr. Peter is a fervent apostle of the old school, and a hater of all microbes. This year he commences with "tuberculosis," and in his opening lecture he attacked the germ-theory as follows: "There are two parties in the field, the old *régime* and the new. The old party believes tuberculosis to be an intrinsic, general, spontaneous disease,—an internal modification of the human structure allied to scrofula. The new theory is that the trouble is extrinsic, the bacillus of Koch being the cause. This wonderful animal may also be found in the supposed-to-be healthy smegma of the prepuce. Lustgarten has likewise found a bacillus in syphilis that is almost identical in shape,—a little thicker, perhaps, but it is much the same thing,—and he claims that it is the *sole cause* of that dreadful disease. Extraneous causes, however, are admitted to have some share in setting up the morbid processes: in fact, this must be added in order to make out a case. It has gone abroad as if with full medical approval, with the sanction of the powerful medical press and that of many of the scientific public, that these microbes are the sole causes of disease, and the practical inference is suggested that if once we can catch them and treat them to a bath of carbolic acid, or some other disagree-

able stuff that may not agree with them (and that certainly won't agree with the poor patient), then we will be all right,—sure to cure, in fact." Becoming warmed with the discussion, the venerable professor said, "Gentlemen, *this is not true*. They mistake, I fear, the lesion for the cause, and confound it with the disease itself. It is possible, by conveying some of these microbes from an animal that is diseased, that the malady can be reproduced, if of the *right kind*,—that is, if they are *wet* and covered with the granulations and the *liquid* which contains the germs of the disease. M. Pasteur has come to tell us that he can inoculate hydrophobia, and you will notice that the marrows are *dried* to extract the poison. Well, many, many years ago, as you know, Gluge told us that there were granulations that he called corpuscles found in the human structure in a state of disease. Will these communicate hydrophobia? Rabies is supposed to be merely a parasite, although they have not as yet isolated it. Never mind: a dog won't bite with his spinal cord, but with his teeth, and the liquids of his mouth certainly carry the disease; but they also carry a host of microbes, among which I suppose it would be very difficult to detect the real one. Passing to cholera, we have been informed lately that the fewer the microbes the more deadly the disease; but this has now gone on so far that I feel it my duty to protest, and I will try to present to you hereafter the other side of the case."

M. Désguin, of Brussels, gives a new method of making an antiseptic dressing that has real merit in case of surgeons in the field, and also for doctors in country places who may be called to dress wounds and not have things ready. As a carrier he proposes to use filtering-paper that has no stiffening in it. It is cheap, and quite as effective as gauze or lint. This paper is to be wet with solutions of carbolic acid of different strengths, or with solutions of boric acid and corrosive sublimate. They are then dried, and are ready for use at a moment's notice by wetting them and applying them to wounds, placing them on sheets of gutta-percha; in this way assuring complete asepsis and allowing the surgeon to carry on the field in small bulk all the dressing he needs to carry out Listerism.

While on therapeutics, mention should be made of the excellent clinical applications that Dr. Dujardin-Beaumetz makes at the Cochin Hospital here. Everything new he tries as soon as it is out, and every year he publishes the results as fast as they can be proclaimed. He has recently issued two works upon clinical therapeutics, and new remedies based upon his service in the Hôpital Cochin.

At the medical clinic, now in full action in Paris, the larger part of the interest is divided between Professor Germain Sée, at the Hôtel Dieu, and Professor Hardy, at the Charity Hospital. Strong and wordy are the discussions which go on between them. Last year they had a great fight over the use of tartar emetic in pneumonia. We give a *résumé* of a late clinic of Dr. Hardy's on sciatica. He said, "I wish to apply before you the treatment for sciatica that is now in fashion,—that is, the chloride of methyl spray. But first I want to speak of this malady and its varieties. Sciatica is not by any means always the same. Its clinical differences often call for particular treatment. It was an Italian—Cotugno, about 1764—who first separated this disease from rheumatic pains and the other troubles that may so often affect the inferior extremity. The history of sciatica is simple. It is pain having its seat along the course of the great sciatic nerve or one of its divisions. The pain is dull,—as a rule, a mere sensation of heat,—but sometimes it is violent enough, so that the patient complains of being torn to pieces, as if he were bitten by dogs or some animal. Its manifestations are very capricious. Sometimes patients do not suffer when warm in bed. This, indeed, is usual. But, again, they may suffer more in bed than when up and about. True intermittent sciatica you will find preventing sleep and going away in the morning. This form you can cure with sulphate of quinine. Valleix well described the particular character of sciatica. These are the ideas he gave, with additions. There are always certain *points* which on pressure will augment the pain. They are situated as follows: 1st, in the vertebral column just above the sacrum; 2d, above the coccyx; 3d, at the level of the great sacro-sciatic notch; 4th, between the great trochanter and the ischium (this is the most frequent of all the points); 5th, just where the popliteus divides; 6th, behind the external malleolus; 7th, on the dorsum of the foot; 8th, on the calcaneum. You will generally find two or three of these points in every patient, rarely more. They often limp from pain, but you must see if this is not from some muscular weakness. It is possible also to find them trembling as in spinal paralysis, or with contracture of the muscles; but this is not frequent. More often you will find, on close observation, that there is a modification in sensibility. Sometimes they are hyperæsthetic, or, again, anæsthetic. A few curious cases have been noted of muscular atrophy. Some patients will complain of cold in the member, the difference not being perceptible to your hand. At other times you will find the part cold, but they do not feel it. When the trouble has existed for some time, you will often find an abundant secretion of perspiration and an exaggerated growth of hair, or, finally, there may be an eruption of vesicules. As a rule, general health is not much impaired. It is well to remember, however, that a sciatica can arise from a compression of a tumor resting on the spinal cord or in

some part along the course of the nerve. The pain here would be persistent and uniform, which will serve to distinguish it from the usually intermittent character of sciatica.

"If the trouble be on both sides, you should be on your guard, for it is an indication of a disease located in the lower portion of the spinal cord. Here you will also observe urinary troubles, such as incontinence or retention of urine. I want to insist on the importance of making the differential diagnosis in all cases between neuralgia and neuritis. If the pain, in place of being localized in special points, is *all along* the course of the nerve, and you find muscular atrophy, cold sweat, and an eruption, then you are in the face of an anatomical alteration of the nerve, a neuritis. Here the diagnosis will be all the more serious in proportion to the duration of the disease. The neuralgia is also serious, as the vast number of remedies prove which have been recommended for it. The best means of treatment are the local ones. Friction with laudanum (pure) will almost always calm the pain for a time, but it will not cure. Good results are also obtained from subcutaneous injections of morphine continued for several days. It is also surprising to see how quickly some cases will give way to injections of chloroform; but it is so difficult to get it pure, and abscesses form from using impure chloroform, so prudence is advised in its use. The old treatment of the days of Cotugno I can also advise. He applied blisters on all the painful points. They are rendered still more efficacious nowadays by being sprinkled with powdered hydrochlorate of morphine. The actual cautery and electricity I would also recommend (the latter a continuous current), but these two don't seem to have won professional support. Hot natural mineral baths also act well; and now we come to the present mode of treatment.

"Dr. Debove has proposed to apply to the sciatic the action of an intense refrigerant, the chloride of methyl spray. In using it you must pass it all over the course of the nerve, and try to freeze all its divisions. Do not let any of the ramifications of its branches escape its action. This is easy, as it will congeal the epidermis and the next layer. This mode of treatment resembles a superficial scarification over a large space, and excellent results have been obtained from it. Should the pain not cease after the first application in certain points, then you may make the application to those points only."

Dr. Vigier made an interesting communication to the Société de Thérapeutique on "Alcohol, Pepsin, and the Alkalies in Digestion," which caused a discussion in which Dr. Paul and others took part, from which it results, first, that a small dose of alcohol increases the acidity of the gastric juice, so that it would be useful in those patients in whom acidity was wanting, hurtful in the opposite sort. Next as to pepsin. It seems that it must not be combined with bicarbonate of soda or other alkali, as the ferment is thereby neutralized. Finally, M. Richet has shown that alkalies given in large doses (five to six grammes) will destroy gastric juice, so that mineral-waters having large quantities of soda and potash salts in them can only do harm in dyspepsia.

Professor Grassat gives the toxicology, hygiene, and therapeutics of sulphide of carbon. Briefly considered, it seems to have quite a number of actions. It has been employed by utilizing its refrigerant properties by evaporation as an anæsthetic, but its best action is as an intestinal antiseptic. Here it is quite efficacious, and not at all dangerous. It has been employed especially in stomach-affections attended by putrid fermentations. The following is the mode of administration:

Pure sulphide of carbon,	10 grammes;
Distilled water,	500 "

Put this in a bottle holding at least seven hundred and fifty grammes, and only take the liquor off by decantation. Then add an equal quantity each time you draw off the water, as the ten grammes of sulphide will be enough to make four or five quarts of liquid. The dose of this liquid is from six up to twenty teaspoonfuls daily (at most, five hundred grammes of it are given), taken in milk or lemonade, or in water with a little mint added.

At a Sanitary Congress of Veterinary Surgeons held in Paris last week, considerable importance was attached to the danger of alimentation with meat from tuberculous animals. Professor Arloing, of Lyons, and M. Lefebvre, of Havre, showed that it was certain, at least in the later stages, that tuberculosis in animals is a contagious disease, and a resolution was passed requesting the government to seize all such meat and have it destroyed. It was also recommended to boil all milk when its origin was not known.

A serious charge has recently been made against certain doctors. The medical profession in Paris appear not to disdain small profits. A report drawn up by Dr. Després on the Night Medical Service reveals a new dodge. This service was organized to enable persons to obtain medical aid at night. This is often difficult, as many practitioners refuse to leave their homes, excepting for their regular patients, unless they are sure of their fees. Under the system established here, persons needing a doctor apply to the nearest police-station, and an officer at once summons one of the medical men on the list, and at the same time he issues an order for the payment of ten francs on the municipal treasury. The person requiring the doctor must repay the treasury, if he can afford it; but, as a rule, it is never reimbursed, and payment is not enforced. It having been remarked that these

visits had increased in a remarkable way,—from three thousand six hundred and twelve in 1876 to eight thousand seven hundred and twelve in 1884,—the city authorities instituted an inquiry, and the report drawn up by Dr. Després reveals some very curious abuses. It seems that some needy and unscrupulous doctors were in the habit of giving the police-officer three francs of the fee every time they were called, and this induced the men to call them on all sorts of pretexts. Besides this, the usual district professionals, who are paid a salary of eighteen hundred francs a year to attend the poor of the quarter in the day-time, had got in the habit of neglecting their visits in the day so that they would be called at night and so get the additional ten francs for night-service. The Municipal Council adopted at once a resolution depriving all medical men attached to the Bureau de Bienfaisance of special fees for night-service.

There are only eight woman physicians on the regular list in Paris. The first was Madame Madeline Brés, who opened the way, she being received in 1865. It seems that at a meeting of the Imperial Council the Empress Eugénie was presiding, her husband being absent, when the application of Mme. Brés was presented. The empress was pleased at the novelty, and asked her advisers to create a precedent in the matter, and she added that she hoped to see the time when Paris would have a woman's hospital exclusively in charge of female doctors. Since that time the other seven have commenced practice. They all do very well. Several more have graduated in late years, but they have not remained in Paris. Three were Americans; and at the present time we have Mrs. Dr. Merritt, of San Francisco, who is about passing her final examinations, having passed all with success with the externat and the internat. As everything is now accorded to women, the way is now open here to the highest honors, and if they are not the coming doctor it will be their own fault. Not the slightest difference is made in the sexes, and they are assigned to any ward, male or female, as it comes, or to male or female subject to dissect, and to the same tables as the men. It seems rather curious for an American to see them helping men to dissect femoral hernia in the male, while doing Scarpa's triangle; but absolute equality is the rule. Paris has also taken a generous initiative in the matter of woman by appointing Mademoiselle Bénoit, a young woman who lately took her degree, medical examiner of girls in the municipal schools. It is her business to see that the girls in public schools are not overworked, and that they study under sanitary conditions. The education of the young in France is certainly destined to fall into the hands of women, and the care of the health of the female portion is now largely under their charge.

The rumor goes that Dr. Mathias Duval is the choice of the Faculty for the place of Professor of Histology left vacant by the death of Professor Robin. It is also said that the eminent doctor will at once commence his course of lectures.

THOMAS LINN, M.D.

PARIS, FRANCE, November 20, 1885.

THE AMERICAN PUBLIC HEALTH ASSOCIATION — THIRTEENTH ANNUAL MEETING.

WASHINGTON, December 11, 1885.

THE proceedings of the Thirteenth Annual Meeting of the American Public Health Association, which ended to-day, were somewhat discounted by the general public interest attending the assembling of Congress and the President's message. Notwithstanding these drawbacks, however, the scientific results of the meeting were of great importance.

The local committee of arrangements, under the active leadership of Dr. Smith Townshend and Mr. J. C. McGinn, made excellent provision for the comfort and entertainment of the members, and the Washington meeting will doubtless be long remembered with pleasure by all who were present.

The first scientific business was the presentation of the report of the Committee on Disinfectants, which was submitted in print, making a pamphlet of about one hundred and fifty pages. The following is an abstract of the conclusions of the committee based upon an extensive series of laboratory experiments:

The most efficient means for disinfecting the discharges of the sick suffering with infectious diseases, such as cholera, typhoid fever, smallpox, diphtheria, etc., are solutions of chloride of lime, 1 part in 25; corrosive sublimate, 1 part in 500; carbolic acid or sulphate of copper, 1 part in 20. For deodorization and disinfection of vaults and cesspools, chloride of lime mixed with plaster of Paris in the proportion of 1 part of chloride to 9 parts of plaster is recommended to be freely scattered over the contents of the vault daily.

For clothing or bedding which has been in contact with the bodies of the sick, boiling in water for at least half an hour will be an efficient disinfectant. If the articles cannot be boiled, exposure to superheated steam for one hour, or, preferably, destruction of the article by fire, is recommended. Fumigation with sulphur, as ordinarily practised, is not to be relied upon. Articles of furniture exposed to infection should be several times washed with a solution of corrosive sublimate, 1 part in 1000; or carbolic acid, 1 part in 50.

For washing the bodies of the sick, a solution of chlorinated soda, diluted with nine parts of water, may be used. A two-per-

cent. solution of carbolic acid may also be employed for this purpose.

The bodies of the dead should be immediately enveloped in a sheet thoroughly saturated with chloride of lime, corrosive sublimate, or carbolic acid solution, to prevent diffusion of the disease-germs.

During the occupancy of a sick-room no active efforts for disinfection, except thorough ventilation, are desirable; but after the room is vacated it should be thoroughly fumigated with sulphurous acid gas, burning three pounds of sulphur to every one thousand cubic feet of space, and carefully closing all openings. After twenty-four hours all surfaces should be washed with a solution of corrosive sublimate, one to one thousand, and thoroughly ventilated before being again occupied.

The report also contains directions for disinfecting rags, infected mail-matter, ships, etc., and concludes with a summary giving exact details as to the proper methods of procedure in all cases where disinfection is necessary.

A suggestive paper upon "Sanitary and Statistical Nomenclature" was read by Dr. E. M. Hunt, of New Jersey. Dr. Hunt proposed the name of "Hygieology"—the science of hygiene—in place of such less definite terms as "sanitary science," "preventive medicine," "state medicine," etc. The paper was a praiseworthy attempt to render the terminology used in hygiene more exact than at present.

An elaborate paper, illustrated by diagrams, was read by Dr. Billings, U.S.A., upon "Forms of Tables for Vital Statistics," and later in the session a committee was appointed to report at the next meeting a uniform method of registration of vital statistics.

Dr. Henry B. Baker, of Michigan, presented a carefully-prepared paper upon "The Relations of Rainfall and Water-Supply to Cholera," profusely illustrated by charts and statistical tables, showing the influence of the stage of the ground-water as conditioned by the rainfall upon the propagation of cholera. Dr. Baker showed, from East Indian records, that cholera and rainfall bore a definite relation to each other, the mortality from the disease being greater in the dry season and diminishing during the rainy period. It was also shown that wherever a pure water-supply had been introduced, the mortality from cholera had been markedly diminished. The lesson taught by these facts should be made use of in our efforts to guard against the disease in this country.

A paper showing much original work and careful observation was read by Dr. D. E. Salmon, of Washington, on "The Virus of Hog-Cholera." This animal plague was declared to be an intensely contagious disease, due to a minute organism which has been isolated and cultivated outside of the body. Inoculation with pure cultures of this organism will develop the disease.

President Cleveland, who had been invited to attend the meeting, sent a letter of regret, which was full of expressions of intelligent appreciation of the work in which the Association is engaged. In the course of his letter the President remarks,—

"Surely the advancement of sanitary science and its practical application to the public health are of immense importance to the people of our land. Of course the value of efforts in the direction of a better understanding of the causes of disease and protection against the same is too palpable for suggestion or argument. But I do not think the advantages of an improvement in the condition and sanitary surroundings of the homes of our workingmen, and of the poor among us, are sufficiently appreciated. Healthful and comfortable habitations indicate the best features of a country's prosperity and advancement, and men with good health and wholesome surroundings are apt to be contented and useful citizens.

"The difference in the death-rate of cities and localities unexplained by natural and inherent causes is of itself enough to give great prominence to the work of the Association, and if this beneficent organization shall succeed, as it ought, in impressing upon municipalities the duty of sensible and thorough sewerage, a plentiful and pure supply of water, and general cleanliness, together with a proper construction of school-buildings for the children of their citizens, it may well point with pride to its achievements."

An eloquent address of welcome was delivered by Mr. Edmonds, the President of the Board of Commissioners of the District of Columbia, after which Dr. James E. Reeves, the President of the Association, read his annual address. This was an eloquent appeal for a deeper interest in sanitary matters by the public and by those who make the laws. The National Government should make provision for the study of contagious and infectious diseases, by establishing a national biological laboratory. The amount expended for such investigations would be abundantly repaid in more thorough knowledge of prevention and cure of the diseases investigated. In touching upon the relations of the National Board of Health and of the Marine Hospital Service to the public health interests, Dr. Reeves steered very successfully between Scylla and Charybdis. Dr. Reeves deserves the thanks of all American sanitarians for his skilful avoidance of offence to either faction in a contest which has heretofore caused much bitterness of feeling among men who should, above all others, work together in harmony.

On the second day of the meeting, Dr. P. H. Bryce, of Canada, read a paper on "Small-pox in Canada, and the Methods of Dealing

with it in the Different Provinces." About three thousand one hundred deaths have occurred from the disease during the present epidemic. In addition to vaccination, exposed persons were isolated for a sufficient period, and infected baggage fumigated. The methods in use were described in detail.

A paper on "Impure Air and Unhealthy Occupations as Predisposing Causes of Pulmonary Consumption" was read by Dr. C. W. Chancellor, of Baltimore. Dr. Chancellor stated that in England one-fifth of all the deaths are from pulmonary consumption, in France one-sixth, and in Germany and Austria about one-seventh. In the census year 1880, the proportion of deaths from consumption in this country was one-eighth of the whole number of deaths from all causes.

In considering the causes which lead to this frightful mortality, Dr. Chancellor said, "Pure air is as essential to the health and vigor of the animal system as wholesome food and drink. When contaminated by stagnation, by breathing, by fires, or artificial light, such as candles, lamps, and gas, it operates as a slow poison and gradually undermines the human constitution. Too little attention is paid to proper ventilation of living-apartments. In some houses the windows are unopened for weeks and months together. Crowds of tailors, seamstresses, weavers, shoemakers, and other mechanics employed in sedentary occupations are frequently pent up from morning until night in close and sometimes damp apartments, without even thinking of opening the windows for a single half-hour for the admission of fresh air. Consequently they are continually breathing an atmosphere highly impregnated with the noxious gas emitted from the lungs and the effluvia perspired from their bodies. The sallow complexions of such persons plainly indicate the injurious effects produced by the air they breathe, and, although its pernicious effects may not be sensibly felt, it gradually preys upon their constitutions, and often produces incurable consumptions, which are frequently imputed to other causes.

"It cannot be denied that some occupations are more unhealthy than others. There can be no doubt that the inhabitants of cities are less hardy and more subject to pulmonary disease than those of the country. City people, speaking generally, are pale, of lymphatic temperament, and their muscular system is but poorly developed. Want of a free circulation of a pure, uncontaminated atmosphere is the most powerful cause of this. In addition, in cities the passions are more excitable, indulgence in eating and drinking is more common, with many life is sedentary, and the occupations are altogether more unhealthy than those in the country. Take, for example, those engaged in mercantile life,—merchants and clerks. These, for sanitary purposes, may be divided into three classes: first, those who have but little exercise, such as book-keepers; second, those who have exercise but are confined to their stores in a superheated, unhealthy atmosphere, as, for example, salesmen; and, third, those who have exercise in the open air, or who do out-door work. In the first class the digestive organs suffer, the next from diseases of the pulmonary organs, and the third from the prostrating effects induced by over-mental or bodily exertion, or by corroding care.

"Persons habitually breathing a dust-laden atmosphere, as the artisans and laborers in some manufactories, are more especially liable to pulmonary complaints. The average duration of life among the dry-grinders of forks is 29 years; of razor-grinders, 31 years; of edge-tool grinders, 32 years; knife- and file-grinders, 35 years; and saw- and sickle-grinders, 38 years. Out of every one hundred sick among the needle-makers, 70 are consumptive; and among the file-makers, 62. Taking the steel-grinders all around, a fraction over 40 in the hundred are consumptive, while one-half of the lithographers—workers in copper—have the disease. Grindstone-makers rarely live over 24 years, and the average life of the flint-cutter and glass-polisher is under 30 years, and that of the stone-cutter, 36.

"The problem of how to face this evil is, simply, how to environ each worker in the prosecution of his work with a pure atmosphere. While waiting for legislatures to accomplish this by legal enactments, it is extremely desirable, and even necessary, that consumptive hospitals should be established in every city. While European cities have provided for this purpose, American cities have generally failed to make such provision. It would be a great and truly useful work to devote an edifice in every large city to so benevolent a purpose."

Dr. E. M. Hartwell, of Baltimore, read a carefully-prepared paper upon "The German System of Physical Education," giving a history of the rise and development of the German systems of turning and physical gymnastics.

"The Debit and Credit Account of the Plymouth Epidemic" was the title of a graphic paper by Dr. Benjamin Lee, of Philadelphia. On account of the lateness of the hour when Dr. Lee's paper was called, it received far less attention than its great merits deserved. No abstract within the space at disposal can do the paper justice.

A paper filled with minute details on "Maritime Quarantine from the Mouth of the St. Lawrence to the Rio Grande" was read by Dr. J. H. Rauch, of Illinois. This was followed by an eloquent account of the system of "Sanitary Protection of New Orleans," by Dr. Joseph Holt, of that city, who devised the new system of maritime sanitation at that port. Dr. Holt said that the

*

people of New Orleans were not yet satisfied that they had secured complete protection, but that they would soon make still further advances towards a thorough and efficient system of sanitary protection against both exotic and domestic pestilences. He insisted upon the absolute necessity of honest and truthful boards of health: these bodies should not be influenced in their decisions by commercial considerations. "Let the world beware," he cried, "of a board of health with commercial alliances in its line of policy. Such a board, with such a policy, is a board without truth!"

Dr. S. T. Armstrong, of the United States Marine Hospital Service, read a paper upon "Maritime Sanitation." The necessity of legislation enforcing the preliminary examination of seamen before shipping was pointed out, as well as the requirements as to cubic space in the sleeping-apartments of the crew.

Professor D. A. Sargent, of Massachusetts, read the report of the Committee on "School Hygiene." The great importance of proper physical training—such training as would develop all the muscles of the body equally—was forcibly dwelt upon. Young people should also be taught the elements of physiology, the necessity of cleanliness, of pure air in houses, etc. These things should not be taught in a perfunctory manner, but pupils should be shown how to apply practically the knowledge gained.

The Committee on Disposal of the Dead reported through the chairman, Dr. John Morris, of Baltimore. An interesting summary of the literature upon the subject during the past year was presented. It was stated that cremation had made great progress in Europe and this country during the year. In France, a bill to legalize the process has been introduced into the Chamber of Deputies. It is proposed to build a large crematorium near Paris. In Italy 396 bodies have been cremated during the year; in Germany, 186. The Spanish Cortes have passed a bill permitting cremation in Spain.

After urging objections to the present mode of disposal of the dead, Dr. Morris said, "If incineration were accepted, all these evils would be arrested. It is generally admitted that this process should be adopted in all great epidemics and after battles; but it would be wise to extend it to cases of zymotic diseases, such as cholera, smallpox, scarlet fever, and diphtheria. These poisons are preserved for years, and at certain times under certain conditions vent their destructive force on the human race."

In a brief discussion which followed the reading of the report, several members dissented from the conclusions arrived at by the committee. It was held that no satisfactory evidence had yet been presented that infectious diseases could be conveyed from cemeteries.

Among the other papers read during the meeting were "The Typhoid Fever Epidemic at Madison, Connecticut," by Dr. C. A. Lindsley, of New Haven; "The Cape Fear River as a Source of Water-Supply," by Dr. Thomas F. Wood, of Wilmington, North Carolina; and "Hygiene of the Dwelling," by G. E. Bell, C.E., of Newport, Rhode Island.

The Lamb prizes for the best essays on sanitary subjects submitted at last year's meeting were awarded as follows:

To Dr. George M. Sternberg, Major and Surgeon, U.S.A., a first prize of $500 for an essay on "Disinfection and Individual Prophylaxis against Infectious Diseases."

To Dr. Victor C. Vaughan, of Ann Arbor, Michigan, a prize of $200 for an essay on "Healthy Homes and Foods for the Working-Classes."

To Dr. David F. Lincoln, of Boston, Massachusetts, a prize of $200 for an essay on "The Sanitary Condition and Necessities of School-Houses and School Life."

To George H. Ireland, of Springfield, Massachusetts, a prize of $200 for an essay upon "The Preventable Causes of Disease, Injury, and Death in American Manufactories and Workshops, and the Best Means and Appliances for Preventing and Avoiding them."

Of the $2800 originally given by Mr. Lamb to be distributed as prizes, under regulations established by the Association, $1700 remain on hand, which sum is to be again offered for competition. In addition, Mr. Lamb, whose generous ardor seems to increase by what it feeds on, has decided to offer four additional prizes of $100, $75, $50, and $25 for plans of three classes of houses for the poor, to cost respectively $600, $1000, and $1500.

On motion of Dr. Billings, Mr. Lamb was elected a life-member of the Association by a rising vote.

The Conference of State Boards of Health, which has hitherto maintained a separate organization, will hereafter constitute a section of the Association, and meet at the same time and place.

Officers were elected as follows:

President, Dr. H. P. Walcott, of Massachusetts.

First Vice-President, Dr. C. W. Covernton, Province of Ontario, Canada; Second Vice-President, Dr. G. B. Thornton, of Memphis, Tennessee.

Treasurer, Dr. J. Berrien Lindsley, of Nashville, Tennessee.

President Cleveland was elected an honorary member of the Association.

After the adoption of several resolutions recommended by the Executive Committee, and the appointment of various special committees, the Association adjourned, to meet in Toronto, Canada, during the first week in October, 1886.

After the adjournment, the members and their friends were entertained by the local committee at an oyster roast, which proved a most enjoyable sequel to an interesting and instructive meeting. G. H. R.

BOSTON.

A POISONING CASE.

SOME excitement has been caused in this community by a wholesale case of poisoning in a house in the most fashionable portion of the city. The symptoms, which at first attacked all the occupants of the house save two young sons and a servant, were those of an irritant poison. A sauce-pan from which the lining had been worn away was at first suspected, and some potatoes which had been cooked therein were analyzed, with the discovery of copper, but in too small quantities, it was thought, to have caused the symptoms. At this time workmen in front of the house were melting tar, and the fumes were very disagreeable to the inmates. The persons who escaped had rooms at the back of the house, which fact led to the supposition that the tar might be the cause of the mischief. But the symptoms continuing, and including œdema of the eyelids, investigation was directed towards the materials used by the workmen to see if they contained arsenic. At this point a fresh and severer outbreak, affecting those previously exempt, recalled attention to the food, and it was found that the boys had eaten for supper of toast made of home-made bread. The boys had not before partaken of this bread. Suspicion was confirmed by the illness of a dog which was fed with bread and milk. The constituents used in the making of the bread were then examined, with the result of finding arsenic in large quantities in the flour-barrel. A few inches below the top of the barrel was a scoopful of a gray substance consisting of a mixture of arsenic and charcoal, probably the substance sold freely by grocers as "Rough on Rats." If this portion had been used in the bread, probably all who partook would have been killed. As it was, the length of time before the discovery of the poison caused serious illness of several members of the family. Even a tramp, who had received a piece of the bread, was found to have suffered. Just before the first occurrence of the poisoning a cook had been discharged from the house, and her place was filled the next day. Suspicion naturally fell upon this person, who might have had the motive of revenge, and she is now under arrest. But up to the present time the police have not discovered who sold the poison, nor have they any positive evidence against her. The statute of Massachusetts forbids any one, under a penalty of fifty dollars, selling arsenic, strychnine, corrosive sublimate, or prussic acid without a physician's prescription unless the seller records the transaction, with the name and amount of the drug, the date, and the name of the buyer. This law at present proves inoperative to prevent the sale of those poisons under the form of various proprietary vermifuges.

Within a few days an unusually distressing suicide of a promising young lawyer occurred in this city, the lethal agent being cyanide of potassium, which was contained in a labelled package with the instruction, "For cleaning coins."

ETHER IN NORMAL LABOR.

The closing meeting of the Obstetrical Section of the Suffolk District Medical Society for last season and the opening meeting for the present season were both largely occupied with an animated discussion on the subject of ether in normal labor. At the former meeting, following a paper in advocacy of the habitual use of ether, the prevalent opinion seemed to be adverse to its employment, except under some special circumstances which might warrant it. The chief objections were the danger to mother and child connected with the anæsthetic itself, the suspension of voluntary efforts by the mother, and chiefly the danger of uterine inertia and post-partum hemorrhage. The most strenuous opposition to these views was offered by Prof. J. P. Reynolds, of the Harvard Medical School, who insisted that the induction of only partial anæsthesia obviated the first two risks, and that as for flooding, that was due to uterine inertia, which, in turn, was due less to any other one thing than to nervous exhaustion. Therefore, he claimed, if the woman is wearied by suffering, relief through anæsthesia is the surest means of averting the danger of post-partum hemorrhage. He remarked that he was then awaiting a summons to a case of special anxiety, through the high social position of the woman, and the fact that she had in previous labors flowed to an alarming extent. Yet, in spite of what had been said of the dangers of post-partum relaxation from the use of anæsthetics, he should consider it his duty to employ ether in her accouchement, for the express purpose of averting this danger.

At the first meeting of the Section after the summer recess, Dr. Reynolds presented a summary of all the cases of midwifery he had had since the previous meeting, including the case above referred to and two others of similar character, when there was particular reason to fear flooding. These he considered would be test cases for the question of anæsthesia, and so treated them. In the whole series of cases ether had been given, usually to the extent merely of obtunding sensibility during the pains, but where forceps were applied, as in some of the cases, to complete anæsthesia. In none of the cases had there

been undue loss of blood or any other abnormality. He was therefore confirmed in his belief that it was the *duty* of every practitioner, on the score of humanity, to afford to all parturient women the relief which might be gained through the use of ether in labor. These remarks applied chiefly to the second stage of labor, as in the first stage he employed chloral and morphia for the same purpose.

A MALPRACTICE SUIT.

One of those unpleasant experiences which are a terror to hospital physicians has recently befallen Dr. Baker, the well-known gynæcologist of this city. A woman who had been the rounds of various hospitals was received into the Free Hospital for Women, of which Dr. Baker is the head. An operation was advised, and its nature, with the possibility of its failure, fully explained. She was even advised to consult her friends before deciding to have it performed. She does this, and repeats to many people what had been told her by the surgeon. From the severity of her suffering, she concludes to accept the operation, and sends for a clergyman, who administers the communion. The operation is performed, and is partially successful. She leaves the hospital, and even expresses her gratitude to the surgeon who has given her his services. The next chapter in the story is the bringing of a suit against the surgeon for ten thousand dollars damages, for having performed, against her consent and without her knowledge, an unjustifiable operation, which had left her crippled. Damages in twenty thousand dollars are also claimed against the hospital which has given her gratuitous board and care. She declared that she was enticed into the hospital on representation that she could there be cured; that she had no suspicion that an operation was contemplated until she overheard the nurses discussing it, and, on expressing her alarm, was assured that nothing would be done without her consent; that she soon after came to consciousness after an anæsthetic to find that she had been made the victim of an operation. She also claimed to have been ejected from the hospital at an inclement season, and at a late hour in the day. At the trial there was testimony from surgeons that she had consulted them beforehand about the operation, and had told them who was to perform it. This evidence was reinforced by that of other persons, including the clergyman. But the case resulted in a disagreement of the jury, and it is reported that ten of the number favored the claims of the plaintiff. It seems to be a dangerous thing, sometimes, to give your services to the suffering poor.

AN ETHICAL QUESTION

of some practical importance has been presented to the Boston physicians for individual solution. Not long ago a burglary occurred at night, which was discovered by a policeman, who arrested one of the burglars. An accomplice attempted the latter's rescue, but was beaten over the head with the watchman's club, which afterwards presented signs of sanguinary use. The case was reported by the policeman, who was confident that he had inflicted serious injury. The following day an order was issued that the patrolmen should call upon every physician in the city, to inquire if any one had on that day dressed scalp-wounds in a man answering to such a description, and, if so, to obtain information which might lead to his discovery. It was believed that the man must have called medical aid. A great many of the doctors who gave negative answers to the inquiry asked themselves the question whether they would be justified in exposing the criminal, supposing they had obtained knowledge of him through his seeking their professional services. There was a rather wide-spread feeling that the police authorities had adopted an unjustifiable mode of investigation for apprehending a man who, though a criminal and one whom all good citizens would wish to see brought to justice, had nevertheless, by coming as a patient, a right to protection from exposure by his professional attendant. If there is a "seal of the confessional," why not a seal of the consulting-room? At all events, the police inquiry was fruitless, which may mean that some physician took this view of the matter.

C. F. W.

Boston, December 2, 1885.

PROCEEDINGS OF SOCIETIES.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held December 3, 1885, A. Jacobi, M.D., President, in the chair.

A review of the life of Louis Elsberg, M.D., and of the advancement of our knowledge of diseases of the throat during his professional career, was read by Dr. M. H. Henry.

The scientific paper of the evening was read by Dr. Samuel W. Smith, and was entitled

ORIGINAL DEDUCTIONS DRAWN FROM A STUDY OF ONE HUNDRED CASES OF FRACTURE OF THE UPPER EXTREMITY, EXCLUDING THE HAND.

The cases observed had come under his care principally during the past four years at the Demilt Dispensary. Nearly one-half of the fractures had occurred in children under twelve years of age, and of these twenty-five were fractures of the clavicle, eight of the condyles of the humerus, and one of the lower end of the radius. Of the cases occurring in persons over twelve years of age,

twelve were fractures of the clavicle, three of the condyles of the humerus, and twenty-four of the lower end of the radius. The author described the nature of the fracture in these cases, which he thought had an important bearing upon the treatment, the principal points being with regard to location, and whether or not the fracture was transverse, short-oblique, or long-oblique. Speaking of fractures of the lower end of the radius, he confined his remarks to the so-called "Colles" fracture, and said he conceived an important difference to exist between this fracture and the short-oblique or transverse, for in the latter case the characteristic deformity of the Colles fracture did not present unless there were at the same time impaction of the upper fragment. But the text-books omitted to mention the peculiar obliquity of the Colles fracture. He said, "The kind of splint used, and the after-management of the case, should, therefore, depend largely upon the fact whether the obliquity of the fracture be long or short. In the former case we have the action of the supinator longus with the extensors constantly drawing the lower fragment upward, and its carpal end with the carpal bones backward and the hand outward, which gives rise to the posterior deformity and appearance of dislocation of the ulna: hence, as the obliquity is great, the difficulty of retaining the fragments in apposition after reduction is correspondingly great, and by the drawing upward of the lower fragment we have a shortening of the radius, giving rise to the unnatural convexity over the head of the ulna so common after treatment of these fractures. Dr. Moore, however, claims that the inner deformity over the head of the ulna is due to the giving way of the internal lateral ligament and the triangular fibro-cartilage, the styloid process and, sometimes, the head of the ulna being thrust through the annular ligament. This may or may not be the case, and is difficult of demonstration. Through the kindness of Dr. Dennis, I was shown a remarkable specimen of so-called Colles fracture, with dislocation of the ulna, the head of the bone tearing through the annular ligament. This specimen was taken from a woman who had thrown herself head foremost from a third-story window, striking upon her hands. The force of the blow was greater than is necessary to produce a Colles fracture: hence the driving of the head through the annular ligament and the comminution of the lower fragment of the radius."

In speaking of these fractures, he used the term Colles fracture only where the fracture was of the long-oblique variety and where it gave rise to the characteristic deformity as discovered by Mr. Colles; the words short-oblique or transverse being employed where the fracture occurs in the same location, but with deformity less marked, and, after the fragments had been brought into apposition, they are more easily held in their natural position.

There were upon his list twenty-five fractures of the lower end of the radius: of these, two occurred in children under twelve years of age, one being transverse and one a separation of the epiphysis with no deformity. Eleven cases were between the ages of twelve and fifty years: of these, eight were short-oblique or transverse, with some deformity, and three were instances of Colles fracture, in which the deformity was well marked; twelve occurred in patients over fifty years of age, and of these two were short-oblique or transverse, with considerable of the characteristic deformity of the Colles fracture, but easily reduced and readily held in position. The remaining ten were Colles fractures, the characteristic deformity being well marked in all of them.

The main object in the treatment of fracture of the clavicle, he believed, is to lift the shoulder upward, outward, and backward, and to hold the fragments in apposition, the dressings in common use being Desault's, Sayre's, and Moore's. In the use of Desault's splint for oblique fracture near the inner third of the clavicle, Dr. Smith had never been able to throw the shoulder sufficiently outward to overcome the deformity without seriously interfering with the circulation of the arm by pressure upon the axillary vessels. One great objection to Dr. Sayre's splint of adhesive plaster is that it irritates the skin and causes superficial ulceration. Dr. Moore's "figure-of-eight" dressing was a step in advance, but it answered the opposite of its intended purpose in oblique fracture near the inner third. This had led Dr. Smith to carry Dr. Moore's idea a step farther by making a clove-hitch with a scarf around the forearm, well up, near the bend of the elbow, passing the loose ends across the back and over the uninjured shoulder. This enabled him to draw the elbow of the injured side farther backward, inward, and upward, and to make the humerus a lever and the side of the chest a fulcrum by which he could lift the shoulder of the injured side upward, throw it outward, and draw it backward. He could thus completely overcome the action of the subclavius muscle, and also that of the sterno-cleido-mastoid by tension upon the pectoralis major, at the same time fixing the scapula and firmly holding the fragments in apposition, without at any time interfering with the local circulation.

With regard to fractures of the condyles of the humerus, a varied experience, full of disappointments, in the use of the known splints for the more severe fractures of the condyles, had set him to work to make a splint which should fulfil the following requisites: 1, to hold the fragments in apposition; 2, to lengthen or lessen the external lateral angle of the arm with fixation; 3, to leave the en-

tire elbow-joint exposed for local treatment during the whole time of wearing the splint without disturbing it.

The instrument which he had devised and now exhibited he described as being made of two rods of untempered steel, extending from the upper part of the arm to the wrist, with a ball-and-socket joint at the elbow and screws for fixation; the lower ends were passed into a sheath-screw upon each side of the wrist; the upper ends passed through two iron posts set in tin and made fast to the arm by plaster-of-Paris bandages, the rods being made firm in the posts by thumb-screws. On each side of the wrist was a post through which the sheath-screw passed and was made fast to the wrist in the same manner as the upper parts, and fastened with fixation-screws. By moving the sheath-screws, the lateral angle of the arm could be contracted or widened as needed, thus overcoming any tendency to loss of the carrying-point. A turn of the fixation-screws at the elbow and wrist would allow the forearm to be flexed, extended, pronated, supinated, and fixed at any desired point, without other interference with the splint.

Regarding passive motion, Dr. Smith thought the time for its commencement varied in different cases. While motion might be wisely commenced within a week from the injury in one case, in another it should not be begun for three or four weeks.

The topic of the treatment of Colles fracture remains for consideration in a future paper. He related some cases, however, and pointed out the danger of leaving a splint on for too long a time without observing the condition of the parts.

DISCUSSION.

Dr. JOSEPH D. BRYANT made some remarks on fracture of the clavicle, and said that he thought the deformity was due to the fact that the clavicle had ceased to serve its intended use,—namely, to hold the shoulder backward, upward, and outward. He did not think the subclavius muscle played any important part in the production of the deformity. Regarding the treatment, the indications were met by Dr. Sayre's apparatus, also by that of Dr. Moore, and also, so far as he was able to judge from casual observation, by the apparatus presented by Dr. Smith. Besides, the latter, of which he thought well, is free from certain objections which pertain to the other two.

Dr. A. C. POST thought the most important distinction to be made with regard to location of fractures of the clavicle was between those occurring in the natural divisions,—*i.e.*, those which occur at the inner side of the coraco-clavicular ligament, those which occur between the coronoid and trapezoid ligaments, and those which occur on the outer side of the trapezoid ligament. In the first situation fracture of the clavicle causes considerable deformity; as the rule, the clavicle is apparently shortened and the shoulder falls, the outer fragment being below the level of the inner fragment. In the second situation there is ordinarily but little deformity, and little treatment was required except rest and support by a sling. In the third situation there is, again, considerable deformity, but of an entirely different character from that accompanying fracture occurring on the inner side of the conoid ligament; in this the shoulder is thrown forward, and the short fragment connected with the acromion is placed at nearly a right angle with the long fragment, and is nearly on the same level; there is no falling.

Dr. A. H. GOELET had used a bandage similar to that employed by Dr. Smith, but made of roller bandage. In a case of fracture of the clavicle in which the adhesive plaster employed in Sayre's method of treatment had given rise to great discomfort, the change had given the patient complete comfort.

Dr. SMITH, in closing the discussion, said he had followed Hamilton's division of the clavicle into thirds. His cases had led him to believe that the subclavius muscle played an important part in the production of the deformity. Only one of his cases was in the outer third of the clavicle.

Dr. C. R. AGNEW offered the following resolution:

"*Resolved*, That it is the opinion of the Academy of Medicine that any judicial or other action which in its effect discourages members of the medical profession in making early reports to the Board of Health of cases of supposed contagious or infectious diseases is contrary to public policy and most detrimental to the interests of public health."

This was carried unanimously, and the Society adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held December 9, 1885, the President, JOHN A. WYETH, M.D., in the chair.

PERINEPHRITIC CYST OF BOTH KIDNEYS.

Dr. T. M. PRUDDEN made the report of the microscopical examination of specimens presented at the last meeting of the Society for a candidate by Dr. H. J. Boldt. The specimens, he said, were of unusual interest and represented a rare condition. One tumor filled nearly the entire right side of the abdominal cavity; a similar tumor occupied the left side, but was somewhat smaller. One contained a litre of gelatinous fluid; the other, three hundred cubic centimetres. They were perinephritic, and the kidneys were besprinkled with small cysts containing a simi-

lar fluid. The fluid in the larger cysts had evidently insinuated its way into the uriniferous tubules, and a part of these were distended to the extent of losing their distinct characters and forming little cysts. One side of the kidney, the side on which the cyst-sac was non-adherent, was smooth, and the renal structure showed marked chronic interstitial inflammation. In the vicinity of the small cysts were hæmatoidin crystals.

Dr. PRUDDEN also presented for a candidate a specimen of carcinoma of the stomach, liver, and omentum.

SARCOMA OF THE LIVER.

Dr. H. J. BOLDT presented a part of a liver which weighed nineteen and a half pounds, and which was the seat of sarcoma. It was of special interest with regard to the difficulty of diagnosis. Some of the physicians who saw the patient thought the condition was amyloid change in the liver, probably due to syphilis, of which disease there was an imperfect history. Dr. Boldt was at first of this opinion, but later changed his diagnosis to malignant disease of the liver. One eye had been enucleated by Dr. Knapp.

CYSTS OF BOTH KIDNEYS AND OF THE LIVER.

Dr. J. W. ROOSEVELT presented both kidneys and the liver, which were the seat of cystic degeneration, removed from the body of a man who entered Roosevelt Hospital July 6, 1883. He was 37 years of age, a laborer, a hard drinker. He had complained for a year of palpitation of the heart and of seeing muscæ volitantes. He had also suffered from headache, dyspnœa on exertion, and œdema. On admission, there was some dyspnœa, respirations 31; the urine was of low specific gravity, and contained five per cent. albumen. The liver and abdominal veins were enlarged. July 12, he became comatose after a severe attack of dyspnœa, and died. There were œdema and old adhesions of the lungs, and some other lesions, the most interesting of which were cysts of the liver, varying in size from that of a lemon down, and of the kidneys. Both kidneys were converted into masses of cysts. Dr. Roosevelt, in the short search which he had made, had been unable to collect more than four cases of the kind.

Dr. ROOSEVELT also presented the bladder and kidneys of a man who had died with symptoms of pyelitis. A stone had been detected in the bladder on admission to the hospital, a few hours before death. One kidney was converted into a small cyst; the other was enlarged,—the so-called surgical kidney. The walls of the bladder were much thickened, and in the viscus was a stone about the size of a walnut.

OSTEITIS OF THE FIBULA.

Dr. WACKERHAGEN presented the lower end of the fibula, the seat of necrosis, removed in the case of a girl, 13 years of age, who, in July, 1882, fell, producing a contusion of the right ankle. An abscess broke spontaneously. Some trouble in the ankle continued until the spring of 1885, when Dr. Wackerhagen exsected two and a half inches of the lower end of the fibula, which had undergone necrosis. The disease had encroached slightly upon the astragalus, which was scraped. The patient made a good recovery, and there were now, seven months after the operation, no signs of disease.

Dr. GIBNEY and the PRESIDENT spoke of the rarity of disease of the lower end of the fibula without involvement of the bones of the tarsus or of the tibia.

RENAL INFARCTIONS; ANTE-MORTEM HEART-CLOTS, ETC.

Dr. L. EMMET HOLT presented the heart and kidneys of a child which had died aged 17 months. It was delicate, and manifested more than the ordinary amount of cerebral irritation during the cutting of teeth. On the last occasion, ten days before death, the disturbance of the brain and nervous system was greater than usual. Drugs had little effect. Two days before death the temperature rose to 104°, the child became comatose, and three hours before death marked cyanosis developed. At the autopsy, the dura mater was apparently normal; there was slight milkiness of the pia; the vessels of the right hemisphere were markedly engorged; those on the left side were apparently anæmic; the same condition was observed in the interior of the brain and in the cerebellum. The cerebral arteries were examined to the second bifurcation, and no obstruction was found. In the left hemisphere the sinuses were occupied by firm decolorized thrombi. This condition was not present on the right side. The heart was apparently normal, but upon both sides were very hard, closely-adherent clots; that upon the right side completely filled the cavity. On the surface of the kidneys were a number of nodules, varying in size from a pea to the end of one's finger. The gross appearances were somewhat suggestive of malignant disease; but the microscopical examination showed white infarction in marked degree. There was commencing diffuse nephritis. Dr. Holt thought the heart-clots were ante-mortem. There was no clear explanation for the post-mortem conditions.

MULTIPLE MYOMA OF THE STOMACH AND BLADDER.

Dr. R. VAN SANTVOORD presented specimens removed from the body of a man 70 years of age, who entered the hospital about two days before death. He was suffering chiefly from dyspnœa. There was considerable fluid in both pleural cavities, and a loud

systolic murmur of uncertain origin. He died apparently from dyspnœa. The autopsy showed pleurisy and fibroid phthisis. The lesions of chief interest pathologically were in the stomach, rectum, and bladder. The stomach was eight inches long, and a saddle-shaped neoplasm, two and a half inches in length and breadth and about half an inch thick, occupied the lesser curvature: it was apparently situated in the muscular layer, and was composed of muscular tissue. The capsules of the liver and spleen and the mesenteries were thickened, and adhesions had formed among the abdominal organs. The liver and spleen were considerably diminished in size; the vessels of the kidneys were in an advanced stage of fibroid degeneration; the bladder contained a circular tumor one inch in diameter and one-fourth of an inch thick, presenting the appearance of a muscular growth; there was also a similar tumor in the wall of the rectum, which was adherent to the base of the bladder by an old process; the aorta was markedly calcareous; the cerebral vessels were very brittle.

THE PHYSICAL SIGNS OF PNEUMONIA.

Dr. VAN SANTVOORD also presented specimens removed from the body of a man who came into Randall's Island Hospital with the following history. On admission, his mental condition was fair, and he said that he had been sick seventeen or eighteen days with a fever and cough, but without expectoration. There was marked dulness over the upper lobe, with flatness over the lower lobe; auscultation revealed absence of respiratory murmur over the lower lobe, and amphoric breathing over the upper. The examination was made by Dr. E. A. Maxwell. On the following day the amphoric breathing had disappeared, and bronchial breathing had taken its place. Over the lower lobe flatness had also disappeared, and bronchial breathing had appeared where there was absence of respiratory murmur before. The urine contained albumen to the extent of one-eighth of its bulk, and there were epithelial and blood casts and free blood. On the last day of his life the patient had three epileptiform convulsions.

Autopsy.—The body was in a fair state of nutrition; the arachnoid was thickened as if by some chronic process, and under it was a quantity of a somewhat gelatinous lymph infiltrated with pus. This appearance covered the convex surface, and at the base extended into the spinal canal, especially on the posterior surface of the cord. The upper lobe of the right lung was in a condition of gray hepatization, and differed from that ordinarily observed in the fact that the consolidation extended very nearly to the anterior edge of the lung, which is free, as a rule, in pneumonia of the upper lobe. This fact was interesting in connection with the physical signs. Dr. Janeway had already called attention to the fact that in pneumonia affecting the upper lobe and extending nearly or completely to the anterior edge there might be not only amphoric respiration instead of bronchial, but also cracked-pot note, because the wedge of lung pressed firmly upon the bronchus and gave rise by pressure to the possibility of cracked-pot resonance on percussion. The left ventricle was considerably hypertrophied; the arteries showed atheromatous change; the kidneys contained a few cysts; one cyst at the upper extremity of one kidney was as large as a turkey's egg; the capsules stripped readily, and the kidney itself had considerable fat in the pelvis, and the process appeared to be one of chronic diffuse nephritis, with great predominance of parenchymatous change; the urine had shown that there was an acute interstitial nephritis, which was the fatal factor in the case. The other viscera presented no lesions of special importance.

CONGENITAL TUMORS OF THE ANTITRAGUS.

The PRESIDENT presented three small congenital tumors, probably composed of yellow fibroid cartilage, removed from in front of the tragus. The father and aunt had had similar tumors.

TUBERCULAR TESTIS.

The PRESIDENT also presented a testicle removed from a man 55 years of age, who had had hernia upon the left side for twenty-five years. About seven months ago the left testicle became enlarged and slightly painful. It gradually increased in size, and six weeks ago extended upward into the inguinal canal, becoming harder and more tender. The patient was more or less constipated, had slight abdominal pains, and pain was almost continuous just below Poupart's ligament. He had lately been treated for posterior spinal sclerosis. The family history was negative. On examination, Dr. Wyeth found a tumor as large as one's fist, evidently containing fluid and extending up the inguinal canal. The diagnosis was possible hydrocele or simple peri-orchitis; there were also indefinite symptoms of strangulated hernia. Operation revealed double cyst, one outside and the other inside the cord; the testicle was enlarged, and microscopical examination would probably show tuberculosis. It was referred to the Committee on Microscopy.

PHILADELPHIA NEUROLOGICAL SOCIETY.

A STATED meeting of the Society was held Monday evening, October 26, 1885, the Vice-President, Dr. CHARLES K. MILLS, in the chair.

Dr. HENRY M. WETHERILL, JR., read a paper entitled

HYOSCINE HYDROBROMATE.

The discussion on Dr. Wetherill's paper* was opened by Dr. D. D. RICHARDSON, who said it had been his experience to find that hyoscine caused dilatation of the pupils. In some cases the pupils remained dilated for a few days, but as a rule it disappeared sooner. The pulse was always much increased; with the exception of one case, it was always above 120. Respiration increased often to 40 per minute. He agreed with Dr. Wetherill as regards rise of temperature and increased respiration. The appetite is not influenced by the use of the drug. The secretions, he said, were generally increased, especially that of the kidneys. No constipation resulted from its use.

Dr. CHAPIN said he had been a daily observer of the experiments of Dr. Wetherill, and entirely concurred with his remarks. He said he had always found the pulse to be hurried. The sleep which resulted from its use has been from eight to ten hours. He thought the difference of opinion as to the physiological actions of the drug might be due to different preparations of it.

Dr. WETHERILL, in conclusion, said that the dryness of the throat was very decided. There was also a relaxation of the muscles of the throat.

The next paper read was entitled

THE PRINCIPLES GOVERNING THE CHOICE OF CURRENTS IN ELECTRO-THERAPEUTICS. BY G. BETTON MASSEY, M.D.

The reader pointed out the value of more accurate conceptions of the differences in the physical character of faradic and galvanic currents as a basis for their intelligent selection. The therapeutic value of faradism is due entirely to its electro-motive pressure, while the most useful medical quality of the galvanic current is its volume.

Electro-motive pressure and electric volume are essentially different articles of the materia medica, and should be so considered.

The therapeutics of "volt-pressure" applications were reviewed, including the differing indications for slow-succession and rapid-succession faradic currents, and were contrasted with the therapeutics of "milliampère-volume" applications.

The paper concluded with the statement that the faradic current presents the best form of electricity for the treatment of those diseases in which a stimulation of mobility or sensibility is either directly or indirectly curative, with the single exception of disorders characterized by the appearance of degenerative response, while the constant galvanic current may be relied upon to fulfil the remaining possibilities of electricity in medicine.

LEWIS BRINTON, M.D.,
Recorder.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, DECEMBER 10, 1885.

The President, J. C. WILSON, M.D., in the chair.

DR. G. E. DE SCHWEINITZ presented a

TUMOR OF THE TESTICLE.

Eighteen months before the first evidences of enlargement of the testicle, the patient had contracted syphilis. This led to a diagnosis of syphilitic disease of the testicle; but the steady progress of the enlargement, in spite of specific treatment, soon compelled a change of diagnosis, with a consequent removal of the organ. One month after this removal the patient died, with recurrence in the abdomen. Microscopic examination of the growth showed a stroma of young spindle-cells, interspersed with variously-shaped collections of cells closely resembling cancer-cell nests. The seminiferous tubules are normal, and their cells are in active proliferation or have passed out into the surrounding tissue to help form the nests mentioned.

Dr. H. R. WHARTON presented a specimen from a case of

GELATINIFORM ARTHRITIS OF THE KNEE-JOINT.

The joint had been diseased for two years, and was excised by Dr. John Ashhurst, Jr. In addition to the usual signs of the disease, the specimen showed a circumscribed patch of caries in the external condyle of the femur.

Also, a larynx and trachea from a case of

MEMBRANOUS CROUP

in which tracheotomy had been performed. The patient, a girl, æt. 4 years, had had croup for some days, when increasing dyspnœa necessitated tracheotomy. After a period of relief, she died suddenly. Post-mortem examination showed a complete membranous cylindrical cast of the larynx and trachea, extending into the larger bronchi. There was also an ante-mortem heart-clot. The exhibitor remarked that the points of greatest interest to him were the great relief following the operation, although there was much membrane below the point of opening, showing that the dyspnœa was due to a certain extent to reflex laryngeal spasm; the extreme smallness of the trachea; the extensive deposit of membrane; and the fact that the tracheal tube might easily have been pushed between the membrane and the inner surface of the trachea.

Dr. CARL SEILER thought that in these cases of croup, as well as in cases of foreign body in the larynx, it was a reflex spasm, rather than the direct obstruction, that caused the dyspnœa. He had found that it is not

inspiration that is interfered with, but expiration. This would lead to the conclusion that the involvement is due to spasm. Now, if it is principally spasm, intubation of the larynx might in some cases supplant tracheotomy: it might at least be tried before tracheotomy is resorted to.

Dr. WHARTON thought that in movable foreign bodies it was the expiration that was most interfered with, while in an impacted foreign body or in an exudation it was the inspiration. This he had been accustomed to regard as a diagnostic point.

Dr. J. B. DEAVER presented a

CONGENITALLY-MISPLACED RIGHT KIDNEY,

taken from the body of a subject in the dissecting-room of the University of Pennsylvania. It was situated opposite the fourth lumbar vertebra, resting upon the aorta and common iliac arteries and veins. It derived its blood-supply from the aorta and common iliac by two arteries. The two veins emptied into the ascending vena cava and common iliac. The ureter sprang from the anterior surface and entered the bladder normally.

Dr. H. A. HARE presented a patient with an

ANOMALOUS HAND,

a negro, æt. 45 years, who had a supernumerary little finger on each hand. Each finger has a nail and is fairly well formed, but is apparently not connected with a metacarpal bone. He has nine children: the first, a boy, has six fingers on each hand; second and third, normal; fourth and fifth, girls, each six fingers on each hand; remaining children normal. He knows nothing of his parents.

Dr. WHARTON SINKLER had had a patient under his observation some years before who had a perfectly-formed and useful supernumerary third finger, which was, he thought, connected with a supernumerary metacarpal bone. He was one of four sons, three of whom had supernumerary fingers or toes, as also had his father and some of his paternal uncles. There were no deformed females in the family.

Dr. JAMES TYSON recalled two instances of this anomaly: the first in a colored boy, whose father presented the same condition; the second in an idiot, with no family history of heredity.

Dr. DE SCHWEINITZ mentioned a case in which this anomaly had passed through two generations. He also referred to a fœtus whose cystic degenerated kidneys he had presented to the Society, in which were present on each side six fingers and toes, in which dissection showed the supernumerary digits to be supplied with supernumerary metacarpal or tarsal bones.

The PRESIDENT had seen several cases of this anomaly in which the supernumerary digit was a mere dermal appendage, situated at the outer side of the hand, near the base of the little finger. Two of these instances had occurred in the same family.

Dr. B. A. RANDALL asked if supernumerary metacarpal or tarsal bones are often to be found in these cases,—a point rather neglected in the previous discussion.

Dr. WHARTON had seen a case in which there was a well-marked supernumerary metacarpal bone, in connection with a perfectly-developed supernumerary finger between the middle and ring fingers.

Dr. H. F. FORMAD had seen a case in which there was no corresponding metacarpal bone, while in the child's grandfather there was a well-developed supernumerary metacarpal bone. The intervening generation was normal.

Dr. W. E. HUGHES said that these, like all other anomalies, were very frequently hereditary, and, again like other anomalies, were much most common in the colored race. There were all varieties of them, from mere dermal appendages, such as are present in the case to-night, to perfect fingers attached to perfect supernumerary metacarpal bones. Between these were cases in which a perfect supernumerary finger was attached to a normal metacarpal bone by a joint separate from the joint of the normal finger. Very rarely there were supernumerary carpal or tarsal bones.

Dr. HARE said that metacarpal or tarsal bones were rare; that dermal appendages were quite common; and that bifid members occupied an intermediate position,

Dr. A. S. ROBERTS read notes on a case of

DEFORMITY OF THE FOREARM AND HAND,

with an unusual history of hereditary congenital deformity.

(To be continued.)

NEW REMEDIES AND CLINICAL NOTES.

TREATMENT OF HEMORRHOIDS.—In an inaugural thesis, Dr. Rosière discusses the treatment of hemorrhoids, and recommends forced dilatation of the sphincter ani as a means of avoiding pain and hemorrhage, except in cases with procidentia without contracture. As regards treatment by cauterization, which is in some cases more suitable, the method of Richet is to isolate the tumors and grasp them with his forceps, which combine crushing with the galvano-cautery. The base of the hemorrhoid is first tied with copper wire, and then the tumor removed with the pincers. The hemorrhoids disappear so quickly as to suggest the idea and name of volatilization. Operating in this way, Richet has treated one

hundred and sixty cases, without having to deplore a single death.—*Revue de Thérapeutique Méd.-Chir.*, No. 19.

Gangrene of Scrotum following Excision of Inguinal Glands.—Dr. W. B. Platt, of Baltimore, communicates to the *Medical News* the records of three cases of limited gangrene of the scrotum following removal of indurated inguinal glands. Within a few days after the operation on the lymphatic glands the bottom of the scrotum became red, swollen, and tender, and a slough shortly afterwards separated, the surface subsequently healing by granulation. The testicles were not exposed. This result occurred in one case in which the original operation was done with full antiseptic precautions. The lesion was regarded as an acute reflex gangrene from intense irritation of trophic nerves.

MISCELLANY.

The Value of a Corpse.—The question whether a dead body is property or not has been before the courts occasionally for adjudication, and has been decided almost always to the effect that it could not be considered as a subject of barter and sale. Some courts have held that there was absolutely no property in a dead body, although there might be in the shroud or coffin. Other courts have held that there was a quasi-ownership which would enable the next of kin to hold possession or remove the body under certain circumstances. The legality of the sale of a corpse for the purposes of dissection has been denied, and judgment refused for the alleged price. A question of this sort came recently before a court at Washington, although the outcome has not been published. It arose in a suit brought by a certain doctor against the demonstrator of anatomy of the medical department of the Georgetown College, to secure payment for a subject said to have been delivered to the college on the order of the demonstrator. The charge was fifteen dollars, which the claimant says was less than usual. Payment was refused, and he thereupon brought suit. The defence interposed was to the effect that the dead body was not property, and that it was stolen from a cemetery. It is said that the latter statement is not denied by the doctor, whose name was mentioned by some of the papers in connection with the stealing of the body of A. T. Stewart some years ago in New York. There seems to be little doubt of the decision of the suit, for the courts have expressly refused to help a creditor trying to enforce a claim of this kind. In addition to this, almost all the States have placed a heavy criminal punishment upon attempts to remove bodies from cemeteries for purposes of dissection.

Butter-Substitutes.—The oleomargarine question is a burning one at every meeting of dairymen, and as a health problem demands the attention of all persons desirous of preventing adulteration in food-products. Almost all of the States have more or less stringent laws on the subject of manufacture or sale, but it is difficult to enforce them. Oleomargarine is manufactured very extensively, and when composed of pure materials and combined in a cleanly manner cannot be said to be unhealthy; but the process of manufacture is not always satisfactory, and the product is almost invariably put on the market as pure butter. This fraud is one which the laws are always aimed at, but the practical difficulty of determining the imitation butter from the real has caused the sales to be immense. The only remedy was thought by the New York farmers to lie in absolute prohibition of all manufacture and sale, and such a law was placed on the statute-book some two years since. Unlike other prohibitory laws, it was vigorously enforced, and there was little oleomargarine either made or sold until the Court of Appeals in that State decided not long ago that the law was unconstitutional, and that a statute prohibiting a manufacture which, when properly carried on, did not produce an unhealthy article of food, was contrary to the spirit of our institutions. Right upon the heels of this decision the oleomargarine-manufactories opened up, and have been in full blast ever since. As a result, it is said that one establishment in New York City has placed upon the market during the past year two million pounds of the stuff, while one in Providence has manufactured one million seven hundred and fifty thousand, and one in Boston one million one hundred and fifty thousand.

The sale of oleomargarine interferes very seriously with that of genuine dairy-products, and the whole farming interest is becoming aroused on the subject. At the recent sessions of the National Butter, Cheese, and Eggs Convention in Chicago some appalling statistics were presented, and a lively discussion took place as to the best preventive measures to be adopted. One of the best suggestions was a demand that Congress pass a general law prohibiting the use of coloring-matter and the sale of oleomargarine for real butter. It is questionable, however, whether Congress will not say that the States must regulate the matter for themselves.

The Publication of the Medical Annals of the United States Navy.—At the regular monthly meeting of the Newport Medical Society held December 2, it was voted that "our associate member, Dr. Ayre, of the United States Navy, who is stationed at the Torpedo Station in this harbor, be requested to personally act with the Newport Medical Society in securing the publication of

the valuable 'Medical History of the United States Navy during the War of the Rebellion.'" A large portion of this material is ready for publication, but, owing to the want of Congressional appropriation, is not available for the use of the medical profession.

The very liberal aid afforded the Army Medical Department in publishing the Medical and Surgical History of the War of the Rebellion, and the acknowledged value of that great work, is sufficient excuse, if any be needed, for pressing the importance of an appropriation for publishing our naval medical and surgical history.

MEDICO-CHIRURGICAL COLLEGE, Philadelphia, December 1, 1885.—Section IV. of the Pennsylvania Registration Law of 1881 requires that diplomas from outside of the State must receive the endorsement of a recognized medical faculty within the State before registration; but, before giving such, the faculty must be satisfied as to the qualifications of the applicant. As the endorsement of a diploma is an acknowledgment of the qualifications of its holder as well as of its genuineness, the faculty of this College desires to announce that it will endorse no diploma for registration until the holder thereof passes a satisfactory medical examination. The fee for such examination is thirty dollars. P. D. KEYSER, Dean; W. F. WAUGH, Secretary.

LIABILITY FOR MISTAKES IN DISPENSING.—The courts have been called upon more than once to determine the liability of a druggist who puts up belladonna by mistake in a prescription calling for extract of dandelion. The latest instance occurred in Iowa, where the facts showed that the customer proceeded to help himself from the jar containing the drug which the apothecary was using to fill the prescription. The customer was injured by the dose he took, and brought suit against the apothecary for damages. The defence interposed was that the customer was a trespasser in helping himself, and could not hold the apothecary liable. This defence was brushed away by the court, which held that if the customer took the dose from the same jar used by the apothecary himself it was under the implied promise assumed by the law that he would pay for what he took, and that in this view he could not be held to be a trespasser. The apothecary was therefore held liable in damages for not knowing what drug he was compounding.

A TIMELY HINT.—The subscription-price of the PHILADELPHIA MEDICAL TIMES is only two dollars a year. *Verbum sap.*

NOTES AND QUERIES.

OBITUARY.

DR. ALBERT HOLMES SMITH died at his home in this city on the 14th instant, in the fifty-first year of his age. He was a native of Philadelphia, educated at the Friends' school at Westtown, and was a graduate of both the Department of Arts and that of Medicine in the University of Pennsylvania. In 1856, when he received his medical degree, he entered the Frankford Asylum as assistant-physician, and subsequently served as resident physician in the Pennsylvania Hospital. He for many years was connected with the Philadelphia Lying-In Charity, to which he was elected attending physician in 1862, and he held this position until one year ago, when the condition of his health was such as to preclude the idea of his being able to resume his active duties at this institution, in which he always took a very warm interest, and where he established his reputation as a successful teacher of midwifery. He also delivered each year a course of lectures upon nursing.

He was instrumental in forming the Philadelphia Obstetrical Society, and was its President from 1874 to 1876. He was also one of the original members of the American Gynæcological Society, and served as its President at its meeting in Chicago in 1884. His contributions to medical literature were, almost without exception, discussions of practical questions in connection with the department of medicine in which he was particularly interested; though not numerous, they gave evidence of original observation, good judgment, and familiarity with the current literature of his branch. He invented several instruments; but that with which his name is best known was an important modification of the Hodge pessary.

In the long months of sickness, from malignant disease of the bladder, his affliction was borne patiently and uncomplainingly, but, when the end came, it was welcomed as a release from suffering which had become intolerable.

Dr. Smith was the type of a Christian physician: he could have no higher eulogy. Modest, cultured, conscientious, and possessing innate refinement, his life was a perpetual rebuke to the impudent self-seeking and greed for gain which are fast assuming prominence in the professional life of the day.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM DECEMBER 6, 1885, *TO DECEMBER* 19, 1885.

CAPTAIN WILLIAM J. WILSON, ASSISTANT-SURGEON.—Ordered for duty as Post-Surgeon, Plattsburg Barracks, New York.

CAPTAIN D. M. APPEL, ASSISTANT-SURGEON.—Ordered for duty at Jackson Barracks, Louisiana.

FIRST-LIEUTENANT H. P. BIRMINGHAM, ASSISTANT-SURGEON.—Ordered for duty at Camp Grant, Riverside Park, New York City.

FIRST-LIEUTENANT GEORGE E. BUSHNELL, ASSISTANT-SURGEON.—Ordered for duty as Post-Surgeon, Fort Preble, Maine.
S. O. 256, Department of the East, December 4, 1885.

FIRST-LIEUTENANT EDWARD EVERTS, ASSISTANT-SURGEON.—Ordered from Department of Columbia to Department of Arizona. S. O. 279, A. G. O., December 5, 1885.

FIRST-LIEUTENANT A. S. POLHEMUS, ASSISTANT-SURGEON.—Relieved from duty at Presidio of San Francisco, California, and ordered for duty as Post-Surgeon at Fort Halleck, Nevada, relieving Acting Assistant-Surgeon Loren N. Clark, U.S.A. S. O. 113, Department of California, November 30, 1885.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM DECEMBER 6, 1885, *TO DECEMBER* 19, 1885.

PASSED ASSISTANT-SURGEON GEORGE C. LIPPINCOTT.—Detached from Navy-Yard, Washington, and wait orders.

PASSED ASSISTANT-SURGEON C. W. DEANE.—Ordered to the U.S. Receiving-Ship "Dale," as relief of Passed Assistant-Surgeon G. P. Lumsden.

PASSED ASSISTANT-SURGEON G. P. LUMSDEN.—Ordered to Naval Hospital, Washington.

PASSED ASSISTANT-SURGEON P. A. LOVERING.—Detached from U.S. Receiving-Ship "Wabash," and wait orders.

PHILADELPHIA, JANUARY 9, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE ON CHRONIC INTERSTITIAL NEPHRITIS.

Delivered at the Philadelphia Hospital

BY JAMES TYSON, M.D.,

Professor of General Pathology and Morbid Anatomy in the University of Pennsylvania, one of the Physicians to the Hospital, etc.

Reported by WILLIAM H. MORRISON, M.D.

GENTLEMEN, — The patient whom you see was admitted to the hospital three months ago. He is 39 years of age, a house-painter by occupation, and during the past fifteen years has had three attacks of lead-colic, the last occurring about two years ago. He has also had other manifestations of lead-poisoning. Four months ago he had a sharp attack of pain in the lumbar region, with vomiting and cramps. The severe symptoms lasted about a week, and then disappeared, leaving some lumbar pain. On admission he had diarrhœa, which was soon checked. Examination of the urine at this time showed that the specific gravity was 1014, and that it contained albumen and small granular and hyaline tube-casts. It was also learned that he had to get up at night six or eight times to pass water. The urine was sometimes pale and at times cloudy. There was slight swelling of the feet. Under the use of iodide of potassium improvement followed.

The fact that a person has had lead-poisoning should always suggest an examination of the urine, for lead-poisoning is one of the recognized causes of contracted kidney. There was in this case a little swelling of the feet, which also directed our attention to the kidneys. You will, however, notice the absence of all other symptoms pointing to renal disease. It is true that he complained of pain, but it will be noted that this pain was of a peculiar kind,—a kind which, when affecting the localities referred to, is almost invariably dependent on lead-poisoning. He had lumbar as well as abdominal pain, with vomiting, lasting about a week, and followed by diarrhœa. Again let me repeat what I have said on other occasions, that chronic Bright's disease of any form is rarely attended with pain, and that pain is not often a symptom of acute Bright's disease. This is contrary to the popular notion, but still it is the fact. More than three-fourths of the cases of "pain in the back" are nothing but lumbago.

Here is the urine. It is pale in color and of low specific gravity, and the quantity is undoubtedly increased. As we have heard, the patient has to get up at night to pass water, and this is one of the characteristic signs of contracted kidney, the presence or absence of which should be promptly determined by inquiry. You will note that testing for albumen by boiling and the subsequent addition of nitric acid gives a faint opalescence. The sediment is very scanty, and includes hyaline and pale granular casts. The swelling of the feet has entirely disappeared, and he feels quite well.

Let me call your attention especially to the small amount of albumen present in the urine. This is another of the most characteristic symptoms of this disease, and there may be even less than in this instance. It is important to remember, in this connection, that the amount of albumen in these cases may at times be so small as to be detected only by the most delicate tests, and sometimes not at all. In no other form of Bright's disease can it be said that albumen is ever altogether absent.

What has been said of albumen is also true of tube-casts in chronically contracted kidney. The sediment is always small, and may contain pale hyaline and granular casts, and these may even be absent at times. On the other hand, casts and albumen both are often overlooked, from want of care in the examination. The casts are always of the hyaline and pale granular variety. It is true that such casts are found in other forms of Bright's disease, and therefore cannot be relied on solely in making the diagnosis; but, when taken in connection with the small albuminuria and the increased quantity of urine, their presence indicates with considerable certainty the existence of chronically contracted kidney.

In these cases the dropsy is small in amount, and in some cases there is no dropsy whatever. It is owing to this absence of dropsy and other marked symptoms that these cases are so often

overlooked. Often the first evidence that the patient is affected with interstitial nephritis is the occurrence of uræmic convulsions. The patient may have previously been in poor health, complaining of nausea, fulness of the head, palpitation of the heart, and uneasiness, but the true cause is not suspected until convulsions set in; and often under such circumstances these end the scene. At the same time, this is by no means invariable; and I now recall a case in which recovery was considered impossible, whereas the patient is to-day journeying to California in tolerably fair health.

Although the symptoms of chronically contracted kidney are often not characteristic at the beginning, yet certain signs present themselves sooner or later. One of the most important of these is hypertrophy of the heart and of the muscular coat of the arteries. Why does this hyperplasia occur? The most rational explanation, although purely theoretical, is this: that in this form of Bright's disease the blood becomes charged with urea and other substances which are effete and poisonous, and it would seem that the arterioles attempt to resist the approach of the urea-charged blood to the tissues by contracting their muscular coat. The heart, feeling this resistance, contracts more powerfully, and the arterioles under this increased force react in turn. In consequence of this action and reaction, hypertrophy results. One of the consequences of this condition of the vascular system is high vascular tension. If the sphygmograph is applied to the radial artery, there will be, instead of the regular up-and-down movement, a prolongation of the systolic factor of the tracing. This is a tolerably constant symptom. Although not pathognomonic, yet it is an exceedingly important symptom to study, and the sphygmograph has here as practical an application as in any form of disease. If this explanation be the correct one in all instances, then it must happen that all forms of Bright's disease which last long enough should, sooner or later, be accompanied by hypertrophy of the heart. This is, however, not the case. I have seen cases of diffuse nephritis extending over many years, during which hypertrophy remained absent. In others, however, it does occur.

Let us now try to determine whether or not any of these symptoms are present in this case. First, as to high tension. This can often be recognized without recourse to the sphygmograph; but where the increase is small an instrument of precision is required. I should say that here there is a slight increase, but it is so slight that I could not assert it without the aid of the sphygmograph.

I shall next examine for hypertrophy, and what often accompanies it, palpitation of the heart. Our patient complains of the latter symptom. We find the apex-beat displaced a little to the left, and the area of cardiac percussion-dulness slightly increased. There is, therefore, evidence of a slight degree of hypertrophy associated with the symptoms of increased tension of the arterial system, as well as palpitation.

Another symptom which is also characteristic is headache and an unpleasant sense of fulness in the head. Our patient has experienced both of these symptoms.

Gastric derangements, especially a morning nausea without actual emesis, are common in this form of Bright's disease, and form a very annoying set of symptoms, persisting day after day. Such symptoms, when obstinate, should always suggest the examination of the urine.

Such patients are also very subject to inflammations of the serous membranes, and it is well to examine frequently, for pleurisy often develops latently.

Dropsy in the early stages of interstitial nephritis is not common, and often remains absent to the very end. More frequently, however, dropsy sets in towards the close of the disease, generally first appearing in the feet.

Owing to the absence of symptoms calling attention to the kidneys, and the presence of others easily explainable in other ways, this form of Bright's disease is frequently overlooked, while, on the other hand, it is the form which is least amenable to positive curative treatment.

The causes of chronically contracted kidney are often as difficult to discover as is the recognition of the disease itself. At the same time, there are well-determined causes, and there is none better demonstrated than lead-poisoning. Another cause, which is more common in England than in this country, is gout. Given a case of well-established gout, and one may be certain that he is also the subject of what is known in England as a gouty kidney,—in other words, a contracted kidney.

Another cause is alcohol, although probably not as frequently as has been alleged. It is the continuous use of alcohol, rather than the intermittent use of even larger quantities, which produces this effect. Still another cause is constant irritation of the genito-urinary passages, such as results from an impacted calculus; and more than once have I known gonorrhœa extend to the bladder and thence to the kidneys and produce interstitial nephritis. Beyond these causes it is impossible to speak with definiteness. It has been asserted that the disease may be produced by anxiety, business cares, and mental disturbances of other kinds.

What is the anatomy of such a kidney as this man is supposed to have? Here are some specimens which exhibit the condition in a striking manner. You see that this kidney is contracted, that it is smaller than natural. It does not weigh more than three or four ounces, while the normal organ weighs from five to seven. Observe the unevenness of the surface, even before the capsule is removed, and when I strip it off the substance of the kidney comes with it. This is characteristic. A closer examination will show an unevenness of the surface, which presents almost a granular appearance; and this is another characteristic. This unevenness varies in different cases. Here it is marked. These granulations, instead of being small, as in the specimen presented, may be larger, often as large as a pin's head, or even that of the head of a nail, whence a kidney of this kind has been called a "hob-nailed kidney." It is also termed the gouty kidney, and, from its appearance, the "red granular kidney," in distinction from the contracted kidney, representing the last stage of chronic parenchymatous nephritis, which is white or yellow. When the kidney is opened, it is seen that the cortex has almost entirely disappeared. It is not more than one-fourth of an inch in thickness. Microscopical examination shows over-growth of connective tissue, and the contraction of this connective tissue has caused compression and destruction of the uriniferous tubules; and in places fragments of tubules with blind ends, and not communicating with other tubules, will be found. This destruction continues until a large part of the secreting substance is destroyed. The proliferated connective tissue undergoes contraction, squeezing and destroying the tubules, just as in interstitial hepatitis the hyperplastic connective tissue contracts and destroys the secreting substance of the liver. It is on account of this analogy that the term cirrhotic has also been applied to a kidney in this condition.

Next as to treatment. In this form of Bright's disease direct curative treatment is scarcely possible. At the same time, patients thus affected may be placed under such conditions that their lives may be prolonged indefinitely. Dietetic measures are more important than medicinal, and of dietetic treatment a modified milk-diet is the best. I do not say that this will cure any case, or that it is the best treatment in every case; but I say, speaking generally, the patient is more likely, under it, to escape the symptoms which cause annoyance and threaten his life than under any other. At the same time, there are often many reasons why this cannot be adopted. It is not necessary that the milk should be exclusive, and I generally permit bread and butter and weak tea. Coffee is not advisable, for its tendency is too much to lock up the wastes of the economy. If the milk-treatment be not adopted, the diet should consist of such food as contains the least amount of albuminous animal constituents, especially red meats. The white meat of poultry, fish and oysters, may be used in preference to the red meat and blood. The objection to meat is that it produces a large amount of urea, and the kidneys are so damaged that they cannot remove it from the blood. Eggs are objectionable for a like reason.

The hygienic measures to be recommended include proper warm clothing, the avoidance of exposure to cold and wet, and care to avoid sudden checking of the perspiration.

There are certain remedies which should not be used. I am satisfied from my own experience that iron is a bad remedy to be used in this form of Bright's disease. In this affection the secretions should be free, the bowels should not be bound, and it is desirable to have rather a poor blood than to have a rich blood. The use of iron tends to increase the fulness of the blood-vessels of the head and predisposes to apoplexy.

Cold bathing should also be avoided, for this drives the blood to the internal organs and increases the risk of rupture of

a blood-vessel. Sea-bathing is dangerous in all forms of Bright's disease, but particularly so in chronic interstitial nephritis.

ORIGINAL COMMUNICATIONS.

PHOSPHORUS-NECROSIS OF THE JAWS.

Read before the American Surgical Association at its meeting held April, 1885,

BY J. EWING MEARS, M.D.,

Professor of Anatomy and Clinical Surgery in the Pennsylvania College of Dental Surgery; Surgeon to St. Mary's Hospital, Philadelphia, etc.

THE earliest observations made with regard to the occurrence of phosphorus-necrosis of the jaws were those of Lorinser, of Vienna, who published a paper upon the subject in 1845, recording cases which occurred as early as 1839; Heyfelder, of Erlangen, and Strohl, of Strasburg, shortly after reported cases and confirmed the observations made by Lorinser. In 1846, Dr. Wilks, of London, published a paper upon the subject in "Guy's Hospital Reports." In 1847 an exhaustive paper was published by Professors Von Bibra and Geist, of Nuremberg, which will be alluded to hereafter. In 1850, Mr. John Simon, F.R.S., delivered a clinical lecture at St. Thomas's Hospital, London, on "Diseases of the Lower Jaw produced by Phosphorus Fumes," illustrated by the report of two cases at that time in the hospital. Other cases were reported, by both English and Continental surgeons, between this period and 1865.

Soon after the report of the cases occurring in Germany, the attention of the authorities was attracted to the subject, and stringent regulations were made with regard to the adoption of preventive measures in the match-manufactories of that country. In 1863, Mr. Simon made a report to the Privy Council of England with regard to the prevention of the disease. His report contained the results of the careful investigations made by Dr. Bristowe upon the subject. In 1867, Mr. Christopher Heath, in the Jacksonian Prize Essay of the Royal College of Surgeons of England, gave a full account of what was known upon the subject up to that date. In this country, Dr. James R. Wood, of New York, was the first to give an account of the disease, accompanied by the history of a case in which he removed the entire inferior maxilla. Subsequently cases were reported in which the entire lower jaw or portions of it were removed by Drs. William Hunt and C. S. Boker, of Philadelphia, and one notable case by Dr. J. C. Hutchison, of Brooklyn, in which the entire upper jaw with the malar bone was excised.

The text-books on surgery contain more or less full accounts of the disease; those of Professors Gross and Agnew treat the subject at some length.

[The account of the process of manufacture of matches, and the description of the effects of the introduction of phosphorus into the system, are omitted here, from want of room.—ED.]

I have had the opportunity of examining a large number of employees in match-factories, and of studying the effects of phosphorus upon them. In sixteen cases I have treated the toxic effects of phosphorus as it appeared in different stages of development upon the system, and I have been interested in observing to what extent toxic symptoms could be traced and defined. Of these cases, the majority has been among those who are engaged in the packing-room, where the handling of the matches occurs; but one was a dipper, and four were cutters.

Of the symptoms described as giving evidence of physiological or toxicological effects, very few have been noted as prominent in the cases under my observation. Beyond instances of conjunctivitis and bronchial irritation, I have not been able to elicit definite information as to any marked effect upon the membrane of the general mucous tracts. Constipation, rather than diarrhœa, has been the condition which existed. Examination of both male and female employees has not revealed any history of aphrodisiac effects, and, in the latter, increase in the menstrual flow has not been noted to any extent. The most marked toxic symptom observed has been the occurrence of hemorrhagic transudations from the gums, and this symptom is frequently noted among the employees. Pain over the region of the liver, sick headache, nausea, and muscular debility are symptoms described by many, while well-defined icterus has not been observed in any case. I have been informed of three fatal cases, in which the immediate cause of death was phthisis,

occurring some time subsequent to operations for the relief of necrosis of the jaw.

It is evident, from the absence of symptoms of acute poisoning, that the invasion of the system by the poison is slow, establishing a chronic toxic condition which awaits some exciting cause to make itself manifest. Accepting as parts of the pathological processes, which follow toxic effects, disintegration of the red blood-corpuscles and fatty degeneration of the arterial walls, we find in the highly vascular periosteum a membrane most liable to exhibit the effects of these morbid changes. Owing to the weakened condition of the arterial walls consequent upon the state of fatty degeneration present, the vascular tension is wholly or in great part lost, and the tissue, while surcharged with blood, is in a state of innutrition, owing to the impoverished condition of the blood: so that I have observed in cases free hemorrhages taking place from gums blanched and apparently bloodless. This condition is most favorable for the development of inflammation, and this process follows promptly upon the appearance of the exciting cause.

In 1847, Professors Von Bibra and Geist, of Nuremberg, published a valuable monograph upon the subject of phosphorus-necrosis, containing a very complete and clear summary of all that had been written previously upon the subject, and also the results of their very careful investigations. The conclusions arrived at were, among others, that phosphorus was the poisonous agent, and that the effects were entirely local. These statements were regarded as proven by the experiments upon rabbits submitted to the influence of phosphorus vapor. In these animals the characteristic disease could only be produced, according to the report, after laceration of the periosteum of the jaw and exposure to the vapor. As the result of these experiments, the deduction was made that the agent acts only when it can come in direct contact with the periosteum, and that those employees in match-manufactories who are free from carious teeth can pursue the occupation with impunity. They suffer neither locally nor constitutionally. The vapor appears to be incapable of producing any general cachexia.

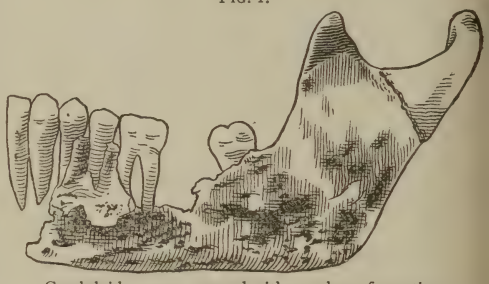
While the observations which I have made confirm, in general, the conclusions stated above, it is my belief that the statement made with regard to the local effects and the introduction of the poison through carious teeth should be received with some modification. I have examined a number of employees who have had carious teeth and were yet free from the disease and have continued to work in the factories exposed to the phosphorus vapors, also those who have had teeth extracted and have returned immediately to work in the factory and have not suffered from necrosis. A number who have suffered from the disease have given, as one of the symptoms which first attracted their attention and caused alarm, the sensation of a protrusion of a number of the sound teeth, or, as expressed by them, an elongation of their teeth. This condition would occur and then disappear, being the result apparently of an accession of cold. In one case the teeth, on two occasions, became quite loose and the gums much swollen and very sensitive. This condition of protrusion of the teeth from the alveoli indicated an inflammation of the peri-dental membrane, a structure which is continuous with the periosteum, and which lines the walls of the alveoli and surrounds the roots of the teeth. In all of the patients whom I have been able to examine in the early stages of the disease, I have found an accumulation of tartar around the necks of the teeth; in some this tartar has existed in large plates extending beneath the gum and covering the bodies of several teeth to the crown. This accumulation is a source of constant irritation, and, being lodged at the point at which the periosteum turns into the alveoli, gives rise readily to irritation of the peri-alveolar and peri-dental membrane. Assuming the correctness of the statement as to the pathological condition which the periosteum acquires as a result of a chronic toxic condition, we find in the carious tooth or in the accumulation of tartar a source of irritation which is competent under favorable conditions to develop inflammation. It is not my belief that the poison impresses the membrane primarily through the carious tooth, as stated by Professors Von Bibra and Geist, or the peri-dental membrane laid bare by the accumulation of tartar around the neck of the teeth which may have caused a recession of the mucous membrane and slight absorption of the alveolar process, but that these conditions, *per se*, under the influence of some exciting cause, as cold,

etc., light up in the periosteum, already in a morbid condition produced by constitutional impression of the poison, an inflammation which, if not arrested, results in necrosis. The pre-existing condition, it seems to me, is therefore a morbid state of the periosteum, which under an exciting cause readily inflames; often exciting causes are found in the teeth; a carious tooth, with the pulp exposed (which structure by some of its tissues is continuous with the peri-dental and peri-alveolar membrane), and with tartar accumulations, gives rise to an irritated and sensitive condition of the borders of the reflected periosteum. It is a matter of observation that the periostitis which develops in connection with other causes (with the exception possibly of syphilis and mercurial poisoning) is in many cases of a local character, whereas that which precedes phosphorus-necrosis is, as a rule, general, passing rapidly to involvement of the entire bone, unless interfered with. In this, as in some other respects, it resembles syphilitic periostitis. In the tertiary form of syphilis the periosteum of the jaws is very prone to inflame under the irritation of carious teeth or the violence inflicted in the efforts at extraction. In the cases of phosphorus-necrosis coming under my care, in the advanced stages of the disease, the uniform statement by the patient has been to the effect that, suffering pain in a carious tooth or in a sound tooth, a visit was made to the dentist and extraction was performed. In a day or two the jaw began to swell, and following that a discharge appeared from the point of extraction,—the history of the beginning of suppurative periostitis caused by the efforts at extraction. In some cases I have found portions of the teeth remaining and the alveolar process greatly broken. The results of the experiments obtained by Professors Von Bibra and Geist upon rabbits are not at variance with the views expressed above, since, according to the statements made, the animals in some instances were exposed for a period of time to the fumes of phosphorus before the periosteum was removed and the bone denuded, and it is quite reasonable to believe that, being easily impressed by the poison, a morbid condition of the periosteum had supervened, so that the laceration of the membrane was sufficient to excite the inflammation. In those animals in which the lower jaw was fractured, laying bare the roots of the molar teeth previous to the exposure to phosphorus vapor, there were evidences, on post-mortem examination, of serious constitutional as well as local effects.

The specific inflammation excited in the periosteum progresses rapidly, and results, in cases of the lower jaw, in the formation of laminated layers of new bone, which envelop the jaw, stopping at the borders of the alveolar process in front and behind, but completely surrounding the angle, ramus, and both processes.

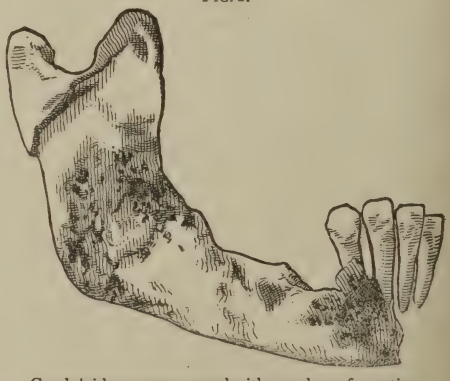
In a number of the specimens removed by me, the new bone formation had encroached upon the articulating surface of the condyloid process (Figs. 1 and 2), and

FIG. 1.



Condyloid process covered with new bone formation.

FIG. 2.



Condyloid process covered with new bone formation.

in one instance completely covered both condyloid and coronoid processes (Fig. 3). An interesting result has occurred in one case under my observation, in which the patient refused operative interference. The necrotic action had continued for six years, and the layers of new bone had united over the position of the alveolar border, thus entirely enclosing the sequestrum, which is

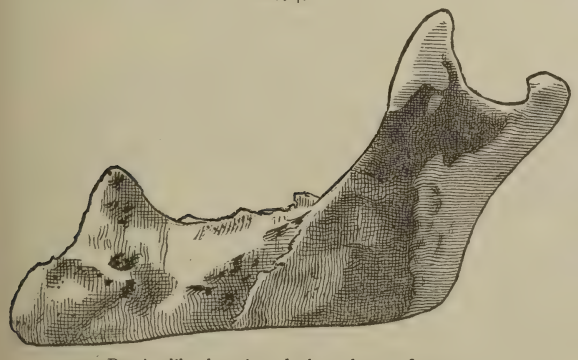
slowly disappearing, the discharge escaping externally by a sinus at the angle of the jaw. The muscles attach themselves to the periosteum covering the new bone, and are lifted off, as it were, with that membrane.

Fig. 3.

Condyloid and coronoid processes covered with new bone formation.

In some of the specimens in my collection portions of the new bone have exhibited the pumice-like appearance described as characteristic of this specific form of inflammation (Fig. 4). This appearance has also been observed upon the surface of the sequestrum. In other instances it has been absent, in this respect confirming the opinion which has been expressed that it is not present in every case, and therefore not pathognomonic.

Fig. 4.



Pumice-like deposit on body and part of ramus.

Professors Von Bibra and Geist have made careful examinations microscopically and chemically of the bone deposited by the periosteum in these cases. It is described as "lamellated, with large Haversian canals, not running *parallel* to the general direction of the bone, but placed at right angles; the lacunæ are rounded off. The proportions of organic and inorganic matter vary, the average being in eight specimens—organic matter, 32.4; inorganic, 6.76."

Mr. John Adams, in a clinical lecture published in the *Medical Times and Gazette*, July 5, 1852, states that these conditions are not observed in bone formed as the result of common inflammation.

Mr. Thomas Smith, in the St. Bartholomew's Hospital Reports, vol. i., reports a case from which he removed the sequestrum of the entire lower jaw, the newly-formed jaw showing on microscopic examination "all degrees of development, from a finely fibro-nuclear matrix up to perfect bone. The bone differs from ordinary compact bone in being excessively vascular, the Haversian canals being very large, near together, freely anastomosing, and here and there in their walls presenting fusiform and pouch-like dilatations,—in fact resembling, in their outlines, veins slightly varicose. The bone is thickly studded with lacunæ, and these are peculiar in being very large in their cavities, less uniform in their general outline, and containing fewer canaliculi than is usual in well-formed bone. In the newest parts of the bone the lacunæ are merely irregularly-formed cavities without distinct canaliculi." These appearances correspond largely with those observed generally in new bone formations, and do not seem to me to be sufficiently distinctive to confine their description to formations occurring as the result of phosphorus-necrosis.

I append the report of Dr. Morris Longstreth upon a specimen of new bone formation taken from one of the cases under my care, and submitted to him for examination:

In the specimen of periosteal outgrowth from the case of phosphorus-necrosis of the lower jaw, two sets of sections have been made,—one vertically to the surface, including the entire thickness of the growth; the other horizontally. The sections (Figs. 5 and 6) show as their striking features the enormous size of the canalization system and the slenderness of the bone-trabeculæ. In the horizontal sections the canals appear of a greater diameter than in the vertical sections. The thickness of the bone-trabeculæ appears about the same in whatever direction

the tissue is cut. The inference to be drawn from this arrangement is that the canals, being connected with the vascular system either of the jaw-bone on the one hand, or on the other with that of the periosteum, have their extension chiefly in the vertical axis. This mode of distribution is evident from a naked-eye examination of the specimen, and is especially evident on its under surface; the upper surface is denser and more compact. It would give a wrong impression to assert that the canalization is wholly in the direction of the vertical axis. The ramification of the canals proceeds in every direction through the substance of the new formation of bone, as can be seen by the varying angles of obliquity at which the canals are found to be cut in the section. The new substance is rather like a sponge, in which the channels of the largest size are in general vertical, as is but natural, since the other channels with which they communicate

FIG. 5.

* The wood-cuts are copied from photo-micrographs taken with a one-quarter-inch lens, natural size about 50 ×.

are seated in the directly subjacent jaw or the superimposed periosteum.

Compared with other periosteal outgrowths originating from other causes than phosphorus-necrosis, it will be seen that the same arrangement of canalization holds true as in this specimen. Here, in vertical and horizontal sections from a periosteal outgrowth from a femur (Figs. 7 and 8), the horizontal sections show larger-sized canals than the vertical sections, while the bone-trabeculæ in these two sets of sections (periostitis of femur) have about an equal thickness. The outgrowth from the femur shows about the same macroscopic appearance as that from phosphorus-necrosis, except that the former is much more dense. The latter may be cut with a knife, the former requires a saw for its division.

Compared with normal bone, the chief direction of the canalization system is found to be governed by the same principles in the normal as in the pathological growth. The law is that the canals pursue the same general course as the blood-supply most nearly contiguous to them. On or near the periosteal surface the canalization is more or less vertical, perhaps tending somewhat horizontally, inclined towards the distal extremity in the long bones. In the deeper layers of the compact tissue of the long bones the canals conform in their direction to the long axis of the bone. In flat bones the canals are almost wholly placed vertically in reference to the periosteal blood-supply. In the periosteal outgrowth the canalization system is found, therefore, to conform to the law governing normal tissue.

In respect to the cellular elements, bone-corpuscles, etc., found in this periosteal outgrowth from phosphorus-necrosis it is impossible to speak, since the specimen is a dried one from which the softer tissues have disappeared.

The lamination which is visible in the specimen, and which is of not uncommon occurrence in periosteal outgrowths, is much more apparent than real. A section made through the junction of the two laminæ, very distinct to the naked eye, does not show to microscopic vision any differentiation of tissue or any disturbance of the arrangement of the canalization system, which is apparently continuous through the two superimposed laminæ. The laminæ are to be regarded as marking the steps of the growth,—a temporary cessation of the formation of the periosteal deposit or outgrowth. The new lamina cannot be regarded as a *de facto* commencement of a new process, but merely as a continuation of the old morbid process, with a very short interval or halt.

With regard to the reproduction of bone after phosphorus-necrosis involving the upper jaw, the cases under my care have confirmed the experience of others who have had opportunities to observe similar cases. In no instance has there been more than a development of fibrous tissue after loss of substance. M. Ollier, of Lyons, records one case of phosphorus-necrosis of the upper jaw in which a certain amount of new bone was produced. He also quotes a case reported by Billroth of a similar character. Mr. Heath, in his work on the jaws, states as his opinion that these cases must be regarded as quite exceptional.

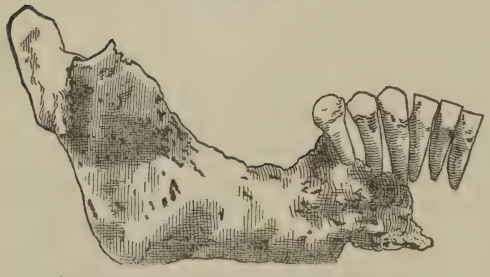
The permanent character of the new bone formation has been called into question by Mr. Salter, who states in his article in Holmes's Surgery, vol. iv., that the "repair of the lower jaw is but temporary; for, after a time,—often a considerable time,—the new bone diminishes by absorption to a mere arch." He has found this state of the bone in one case in which the lower jaw had been removed ten years, and asks as a question of theoretical interest and of practical importance how far this loss can be prevented by supplying it with a function through the means of artificial teeth. While more or less absorption does undoubtedly occur, it has been my observation that this condition is affected largely by the period of time in the deposit of the new bone at which, and the manner in which, the operation for removal of the sequestrum is performed. If removal of the sequestrum be delayed until well-formed plates of bone have been deposited, and care be taken in separating them from the sequestrum to avoid their fracture or dislocation, the absorption which naturally follows will not seriously impair the permanent character of the new-formed bone (Fig. 9). In one case in which I operated in 1881, removing two-thirds of the lower jaw, from the articulation on the right side to the first molar on the left, the new bone formation has not exhibited any marked decrease in size up to this period, and the patient has been able to wear with comfort and satisfaction an artificial denture for the past three years (Fig. 12). In another case, in which a large portion of the new bone deposit had been removed as a primary operation and with the intention of interfering in this manner with the progress of the disease, another layer of bone formed from the periosteal surface, which, however, lacked the density and firmness of

the lamellæ deposited originally; as a result, a greater degree of deformity occurred in the case than in others in which care was employed to remove the sequestrum without disturbing to any extent the new bone formation. Whether the adaptation of artificial dentures will in any degree diminish the tendency to absorption is to me a question: it would seem that the pressure exerted and friction produced by the movement of the denture upon the newly-formed and rather imperfect bone would develop absorptive action rather than diminish it. Notwithstanding, I always endeavor to have dentures adapted, in order to supply the loss so much felt by patients.

FIG. 9.

Appearance of patient after removal of right half of lower jaw; new bone well formed.

FIG. 10.



Sequestrum removed from patient shown in Fig. 9.

With regard to the relative frequency with which the upper and lower jaws are attacked, the cases under my care have shown a decided proportion in favor of the lower jaw. Out of sixteen cases, the lower jaw was involved in eleven, and the upper in five; in three both upper and lower jaws were attacked, the upper in a much less degree than the lower. This preponderance in favor of the lower jaw has been observed by the German and other authorities. Of fifty-two cases reported by the former, as stated by Mr. Heath, twenty-one were of the superior maxilla, twenty-five of the inferior, and five in which both were involved. Mr. Salter (Holmes's Surgery, vol. iv.) records five

FIG. 11.

FIG. 12.

Appearance of patient with artificial denture after removal of two-thirds of lower jaw from right side.

cases under his care, in four of which the lower jaw was diseased, and the upper in one. In seventeen instances of which he obtained information, nine were connected with the superior and eight with the inferior maxilla. In Agnew's analysis of one hundred and eleven cases, fifty-eight were of the lower and forty-one of the upper, with twelve in which both were involved. From the information I have been able to obtain with regard to cases occurring in this country, the lower maxilla appears to have been attacked more frequently than the upper. These cases show, as in those under my care, that the upper jaw is not, as a rule, involved to the same extent as the lower,—the disease being limited rather to the alveolar border. This comparative immunity enjoyed by the superior maxilla is to be explained, it seems to me, by the difference in the configuration, the character of the structure, and the blood-supply of the two bones. The presence of the sinus within the body of the superior maxilla, lined by a membrane endowed with a good blood-supply, would enable the bone to resist the advance of the necrotic action. The absence of a large amount of cancellous tissue, as compared with the lower jaw, would also favor this immunity, although Mr. Heath is of the opinion that necrosis occurs less frequently in cancellous than in compact bone. Such has not been my observation in connection with necrosis of the lower jaw arising from various causes, since in many instances the dense compact base of the bone seemed, as it were, to afford a barrier to the advance of the disease.

The symptoms of phosphorus-necrosis differ from those of ordinary necrosis mainly in intensity. The pain, which is one of the earliest symptoms, is at first intermittent, but in time becomes continuous. It is also more diffuse from the first, involving the entire bone. The first and second stages are, as a rule, rapidly passed through, and suppurative periostitis manifests itself in the peri-alveolar and peri-dental membranes, causing the teeth to become loose and pus to exude from the alveoli. The inflammation quickly extends, involving the structures of the gums, and detaching them so as to expose the alveolar border. Infiltration of the tissues of the face follows, and swelling, which produces marked deformity, occurs. Soon the inflammation invades the entire periosteal layer, the formation of the laminated bone can be distinguished, and offensive discharges escape into the mouth; in the case of the lower jaw, the pus gravitates to the base and escapes by sinuses at this point (Fig. 13) or at some point

Fig. 13.

Necrosis of left half of lower jaw, with sinuses opening at the base.

lower down. In one case under my care the sinus had opened at the upper border of the clavicle before the patient presented herself to me for treatment. In some instances the pain continues during the suppurative action; as a rule, it is much diminished or disappears. When the inflammation involves the condyle of the lower jaw, great pain is experienced in the ear of the affected side, and occlusion of the jaws, which before may have been partial, now becomes complete. The interference with the ingestion of proper food, owing to the condition of the mouth; the suffering endured by the patient, associated with the constant presence in the mouth, and the swallowing, of the offensive discharges from the dead bone,—all combine to deteriorate in a marked degree the general health of the patient. Unless proper remedial measures are resorted to, death may ensue from exhaustion, or, in very severe cases, from gangrene of the overlying soft structures. In rare instances, such as the one alluded to in another part of this paper, the disease may assume a chronic form and the general health may be maintained during a period of years, while the sequestrum slowly dis-

integrates and the débris is carried off through sinuses.

The treatment may be divided into that of three stages: primary, intermediate, and secondary. The primary stage may be described as that in which the periosteum, in its morbid condition, manifests the results of beginning irritation. Unless alarmed by the occurrence of necrosis in a fellow-workman, the patient rarely presents himself for treatment in this stage. Pain in the bone of a diffused character—intermittent in occurrence, with the sensation of protrusion of the teeth—and soreness in the gums, with hemorrhagic transudations during mastication or upon the use of the tooth-pick, are the chief symptoms present in this stage. An examination may reveal one or more of the teeth in a carious condition; around the necks of the diseased as well as of the sound teeth a collection of tartar extending some distance beneath the gums and displacing the soft tissues; a softened condition of these structures, with a discoloration of a purplish hue. In this stage the treatment relates to the condition of the teeth, which should be conducted with the utmost care in order to avoid the production of periostitis, and the administration of remedies which are antidotal in character. Those teeth which are too much diseased to be saved by treatment should be extracted, especial care being taken to avoid fracture of the tooth or of the process. Collections of tartar should be thoroughly and carefully removed, the instrument being carried well up under the gums to remove any that may be lodged in this position. The carious teeth should receive careful treatment, so as to relieve the sensitive condition which exists and to avoid by gentle manipulation the development of peri-dental inflammation. Temporary fillings should be inserted until such time as it may be prudent to employ those of more permanent character. The soft structures should be bathed with detergent and astringent lotions, as phenol sodique, alcohol, tincture of myrrh, etc., in dilute solutions.

The constitutional treatment should consist in the administration of anodyne remedies, to relieve pain and soothe the general system, and of that agent which is regarded as possessed of the power to neutralize the effects of the poison and arrest the disease. Dr. Letheby, in his work on "Chemistry of the Poisons," recorded his observations upon the power of the vapor of turpentine to neutralize that of phosphorus. Andant, quoted by Bartholow, was the first to report cases in which the antidotal properties of turpentine were observed; and Personne, by experimental demonstration, confirmed the observation of Andant. The latter further inferred that, "as turpentine destroyed the luminosity in the dark and arrested the escape of the vapor of phosphorus, it acted similarly as an antidote in preventing the combustion of phosphorus in the blood and the consequent consumption of the oxygen." Höhler and Schimpf (Bartholow) showed by experiment that the commercial oil of turpentine (that which had been exposed for some time to the air and was therefore rich in ozone) was the only variety efficient as an antidote; that this form prevented fatty degeneration of the tissues; and that while under its influence no free phosphorus could be found in the animals experimented on.

In the cases which have come under my care, five have presented themselves in the first stage of the disease, and in these I have been enabled to employ the plan of treatment outlined above. In two, treated some three years since, the disease was arrested in the primary stage. At present I have three patients under this plan, and in these there are positive evidences of improvement.

In the stage which I have designated as the intermediate, in which the inflammation of the periosteum is well established, the plan of treatment should be such as to arrest, if possible, the inflammatory action, and thus limit the destruction of bone. Active antiphlogistic measures are here indicated; free incisions of the periosteum, the knife being carried to the bone, should be employed, and the use of such internal remedies as will assist in combating the condition of inflammation. According to my experience, the efforts to arrest the progress of the disease in this stage are, as a rule, without much avail: the specific character of the inflammation, so far as relates to its cause, and the rapidity with which it becomes general, seem to resist any successful interference. Measures should always be adopted, however, with the hope of at least limiting the subsequent necrosis.

When the inflammation has passed to

the suppurative stage and the death of the bone is accomplished, the treatment should consist in that which is supportive and expectant. Warm water should be freely used to cleanse the mouth, after which very dilute solutions of carbolic acid, iodine, or permanganate of potassium should be thrown upon and around the exposed bone with a syringe, so as to disinfect the parts and remove the collections of pus. A layer of seven-and-one-half-per-cent. iodoform gauze should be packed around the exposed bone so as to receive the secretions and prevent as far as possible their escape into the mouth and mixture with the food. If sinuses have formed, they should be cleansed by injections of medicated solutions as advised for the mouth, and a mass of iodoform gauze and cotton should be placed over the openings and held in position by a bandage. Poultices and warm fomentations should not be applied to the face, as they increase the suppurative action and invite the flow of pus to the surface, resulting in the formation of sinuses and consequent disfigurement. Nothing should be done to interfere with the bone-reproduction. No efforts at removal of the sequestrum should be made until the necrotic action is completed and the reproduced bone is sufficiently firm to preserve the shape of the original bone. In three of my earlier cases I endeavored to arrest the progress of the disease by cutting away the exposed process and scraping off the periosteum with the layers of new-formed bone. In no instance was the operation successful in stopping the disease, and the deformity which followed the subsequent removal of the complete sequestrum was greater than in cases in which this plan of treatment was not attempted.

The sequestrum should be removed through the mouth, care being taken to separate the laminæ of new bone entirely, so that they will not be fractured or drawn away with the sequestrum. When the disease has invaded the condyloid and coronoid processes of the lower jaw, the disarticulation is easily effected after incision of the structures in front of the ramus. In some instances it may be necessary to divide the ligaments of the articulation with the probe-pointed bistoury. When the entire lower jaw is involved, I have found it desirable, in order to preserve the contour of the parts, to remove but one-half at a time. After the expiration of eight or ten weeks, the remaining portion may be removed. (Figs. 14, 15.)

Fig. 14.

Sequestrum representing entire lower jaw. Right half removed ten weeks subsequent to removal of left half.

Fig. 15.

Appearance of patient after removal of the entire lower jaw.

After the removal of the sequestrum, the cavity between the two layers of new bone should be cleansed and packed with seven-and-one-half-per-cent. iodoform gauze; at each dressing the quantity used should be lessened, in order to permit of the approximation and consolidation of the bone-plates. For some time after removal of the sequestrum in the lower jaw, a bandage should be applied so as to support the new bone. After removal of the sequestrum in the upper jaw, the same form of dressing should be used until the

cavity is closed by the fibrous tissue which forms, as a rule, in place of the bone.

During the period of suppuration, the strength of the patient is to be maintained by the administration of preparations of iron and quinine, concentrated food, and well-regulated exercise in the open air. Care should be taken to avoid exposure to cold, and the hygienic surroundings should be carefully attended to.

The prevention of the disease is to be accomplished by the joint efforts of employers and employees. The introduction into the manufactories of systems of ventilation which will promptly remove the phosphorus fumes and as well the smoke from burning matches, will contribute materially to prevent the occurrence of the disease. While this may be accomplished successfully so far as relates to certain parts of the works, there are practical difficulties in the way of securing it in those rooms in which the matches are handled and constantly igniting, owing to the great danger which would arise from serious conflagrations if currents of air sufficient to remove the fumes and smoke were introduced. Efforts should, however, be made until some safe method is devised to accomplish this. In one factory with which I am familiar, exhaust-fans have been arranged so as to remove the fumes promptly from over the dipping-machines. Since the introduction of this plan, the employees working at these machines have been free from disease. Experience has proved the value of turpentine in neutralizing the toxic effects of the phosphorus fumes; and, as in the factories in England and on the continent of Europe, the employees in this country should protect themselves by wearing open, wide-mouthed bottles containing this agent, suspended by straps around the neck so that they should rest upon the anterior surface of the chest, affording in this way ready inhalation of the vapor. At various points in these rooms, protected from fire, large shallow vessels containing turpentine should be placed, in order that its vapor may come in contact with that of the phosphorus and neutralize it. The substitution of amorphous phosphorus, which does not fume, for the common phosphorus in the manufacture of matches has been recommended. The chief objections to its use are the cost, which is stated to be double that of the common phosphorus, and its want of ready fusibility. The safety match, which is being gradually introduced into use, is stated to contain no phosphorus. The chemically-charged paper attached to the boxes is said to contain amorphous phosphorus, and the manufacture, therefore, of this form of match should be free from danger.

On the part of employees, immunity from danger can be secured by the use of turpentine (as suggested above), frequent inspection of the teeth, and cleanliness. Inspections of the teeth should be made frequently, all accumulations of tartar should be removed, and carious teeth carefully extracted or treated and filled. During the treatment of the teeth or immediately after extractions the patient should not engage in work in the factory. Careful washing of the hands before taking food should be insisted upon and enforced by those in authority, and if it is necessary that the noon meal should be eaten in the factory, a special room should be provided for this purpose separate from the others.

I feel quite confident, from the investigations made by me in connection with the cases which have been under my care, that it is possible, by the adoption of proper methods of ventilation in the factories and the enforcement of proper regulations relating to the employment of antidotal agents and strict attention to cleanliness, to prevent the occurrence of the disease. It affords me pleasure to state that the largest manufacturing establishment in this country, The Diamond Match Company, which exercises the most liberal care of those attacked with the disease, is also keenly alive to the importance of securing its prevention by all available means.

I desire, in conclusion, to submit the following propositions:

1. That the disease is a local expression of the constitutional condition produced by the inhalation of the vapor of phosphorus, and by particles of the agent taken into the system with food by operatives in match-factories who do not give proper attention to cleanliness of the hands.

2. That the introduction of the agent into the system is, as a rule, very gradual, and in such small quantities as to avoid the production of symptoms of acute poisoning; that in this way the chronic toxic condition of the system is induced, characterized chiefly by disintegration of

the red blood-corpuscles and fatty degeneration of the arterial coats.

3. That the toxic condition precedes the jaw-disease, as is shown by the fact that the disease does not attack operatives recently exposed to the action of the agent, but those who have been exposed for a period of years.

4. That examination of the teeth of operatives has shown that many who have caries, and have returned to work immediately after the extraction of teeth, have enjoyed immunity from the disease, showing that the agent had not attacked the periosteal tissue thus exposed. This was further shown by the fact that in one of the cases necrosis did not appear until three months after labor in the factory had ceased.

5. That individuals vary in their susceptibility to the action of the poison. For this reason many suffer immediately with acute symptoms, such as nausea, vomiting, etc., and are compelled to abandon work in the factories.

6. That the conditions under which experiments have been made on animals, to prove the absence of the disease until exposure of the periosteum and perialveolar tissue was effected, are not similar to those to which operatives in match-factories are subjected.

7. That treatment of the disease in the primary stage is efficient and prevents its progress.

8. That the antidotal powers of turpentine have been established.

9. That the disease is to be prevented among operatives by the adoption of thorough methods of ventilation, stringent rules with regard to cleanliness, and the free disengagement of the vapor of turpentine in all the apartments of factories in which the fumes of phosphorus escape.

THE PENNSYLVANIA HOSPITAL AS A TRAINING-SCHOOL FOR PHYSICIANS.*

BY HENRY H. SMITH, M.D.,
Philadelphia.

WHEN the happy thought of our friend Richard Cadbury, the able steward of this hospital, led in June last to a social gathering of those who had served or were serving the institution as resident physicians, it brought together not only the few who dated back nearly half a century, but also many of those of a more recent period.

At this meeting, the pleasure excited by the renewal of old associations was very apparent, whilst the varied anecdotes and "inedited legends" of the house showed that the course of the Pennsylvania Hospital in the relief of the sick and destitute continued onward.

The acquaintances then renewed or formed between the residents of various periods proved that the bond of union was the pride each one took in the institution he had served in his youthful days, all admitting the professional benefits derived from this his former field of service.

At this gathering pleasant memories were revived by speakers representing the various decades of the service of the residents then present, and sad reminiscences followed the mention of such as were removed from our circle by the hand of death.

After enjoying "the flow of soul" of our excellent host of that evening, in aqua pura frigida, it was resolved that "the feast of reason" should be inaugurated by creating an organization that, meeting annually, would preserve the fraternal ties of professional interest made evident by so large an assembly, and indicate the value of the Pennsylvania Hospital as a training-school of physicians.

Having been recently requested by our executive committee to read on this occasion "a paper on any subject that might suggest itself," I have cheerfully assented to their wish.

Permit me, then, briefly to allude to a few of the important results gained by our profession and the public from the development of this hospital as a clinical school. As this can be best demonstrated by reference to some points of practice that originated in its wards, I shall allude to a few with which I am familiar either by study or personal observation, leaving to others of those present the pleasant duty of anecdotical reminiscences of their experience as residents of this hospital.

That the wards of this hospital have largely contributed to the relief of thousands is well known everywhere, but their special utility as an educational means has not been so distinctly alluded to from the

* Read at the first annual meeting of the Association of Resident Physicians of the Pennsylvania Hospital, December 17, 1885.

stand-point of those who resided in the house.

As the resident physicians of each term gained much of their practical skill from the experience and precepts of the attending physicians and surgeons, I propose, in illustration of this point, to rapidly enumerate a few well-known subjects which, starting in the practice of the hospital, were subsequently developed for the benefit of the health and lives of many families throughout our country, by residents who subsequently became their medical advisers.

To specify a few of these, prominently brought to the knowledge of the profession by such men as Physick, Hartshorne, Parrish, Hewson, Harris, Barton, Randolph, and others of a more recent day, is all that time will now admit,—such as the paper of Physick on "The Use of Animal Ligatures," published in the *Eclectic Repertory** in 1816, in which he proved, by experiment, that ligatures of buckskin, parchment, and catgut were readily dissolved, but that catgut was the most enduring: so its recommendation by recent gynæcologists is nothing new. Hartshorne's, Parrish's, and Hewson's experiments on the best means of arresting hemorrhage were likewise performed in connection with this institution.

The invention of Parrish's needle for ligating deep-seated arteries, that was so useful as to be afterwards claimed in New York, was another item; and Physick's cure, in 1802, of John Hius's false joint in the humerus, by introducing a seton between the ends of the bone, not only instructed those who saw the case, but the bone, which is yet in the Wistar & Horner Museum,† continues to enlighten generation after generation of medical students by showing the increased nutrition in bone thus excited.

Barton's operation for the relief of an anchylosed hip-joint, and that of wiring a fractured patella in 1834, were performed in our surgical wards, and the latter is now being revived in practice after lying dormant so many years, although the unfortunate result of his case has not always followed. In this house Randolph made his reputation in lithotripsy in the patients he so brilliantly cured in 1837 to '39.

Nor was the instruction of the hospital limited to its surgical wards. At an early period (1803) Benjamin Rush drew much of the knowledge he so widely disseminated in his lectures and "Medical Inquiries" from its patients; and it should not be forgotten, when Pasteur is now directing attention to the prevention and cure of hydrophobia, that Rush detailed an autopsy of a case of hydrophobia, and urged the adoption of Physick's proposed operation of tracheotomy or laryngotomy to obviate the effects of the spasm of the glottis that causes death in this dreadful disorder.‡ To Dr. Rush has also been assigned the suggestion of the cure of intermittent fever by pills made of cobweb,—the secretion of the spider known as the *Araneæ tela*,—a remedy which is said to have been originally prescribed by Dioscorides in the second century for the same purpose. As history repeats itself, this remedy has been recently (1885) revived by Dr. MacDonald, of New York City, for the same disorder; he recommending a tincture formed by macerating for forty-eight hours a bunch of cobweb of the size of a large walnut in f℥iv of whiskey, and then filtering. Of this a teaspoonful is to be taken every hour for four hours before the expected chill, etc.

Another item connected with the practice of a former day may be recalled in the fact that here Otto, with his rough pharmacy, in Parrish's cider and horse-radish mixture, cured dropsy, or relieved rheumatism with guaiacum and the decoction of the woods, as promptly and effectually as by propylamine, salicylic acid, or any of the more finished prescriptions of the present day; and it was likewise in these medical wards, as is well known to many, that B. H. Coates, Gerhard, Stewardson, and Wood pointed out at various periods, in post-mortem demonstrations, the changes created by disease in fevers and affections of the chest and abdomen.

It is, however, to the results of the labors of our former residents, rather than to those of the staff, that I now desire to direct attention.

The resident physicians of this house, in the early days now alluded to, had special opportunities for gaining knowledge. During the years prior to 1850, *this* was the main hospital of our city. The Almshouse, which until 1834 was on Spruce

* Vol. vi. p. 389.

‡ Medical Repository, vol. i. p. 105, 1804.

Street, between Tenth and Eleventh, only presented the student with chronic cases of disease in worn-out systems, and did not usually receive recent accidents, nearly all of which, if happening within twenty-four hours' travel of this city, were brought to the Pennsylvania Hospital; and I can recall one 1st day of May when seven severe cases of fracture were received on that day. At this period there were but two resident physicians in the house, each of whom served two years, and alternately took charge for six months of about two hundred insane cases, the male and female medical wards, as well as the obstetrical ward at the "Picture-House," on Spruce Street, each case of labor being attended in turn by each resident; or of both male and female surgical wards, where not unfrequently there were eighty beds to be dressed each day. The attending physician, surgeon, and obstetrician then only visited the wards on Wednesday and Saturday, as a general rule, unless in the judgment of the resident the case was so serious as to demand an immediate or more frequent consultation. The care of the insane alone was a heavy duty; and when the house suffered from the frightful mortality that attended two severe epidemics of puerperal fever, and which, strange to say, were always attended by a severe epidemic of erysipelas in the surgical wards, one being on Spruce Street and the other on Pine, notwithstanding all precautions taken in non-intercourse of attendants, it may readily be seen that the office of a resident physician was no sinecure. Twenty years' experience in private practice could not furnish such opportunities as then existed for a resident physician to gain a varied knowledge of his profession and to acquire habits of industry and self-reliance in emergencies, that never afterwards deserted him.

Prior to 1840 the insane patients occupied the portion of this building usually designated as the "West End," where Captain Poirier, in excellent French, instructed every one in the "Code Napoléon" and its application to all who unjustly restrained him of his liberty; and it was in the care of these patients that a resident in 1834–35, though specially interested in surgery, laid the foundation of that knowledge of insanity that, after 1840, as physician-in-chief of the department of this institution in Blockley, made him so widely known as an alienist that the public usually designated the Department of the Pennsylvania Hospital for the Care of the Insane as "Kirkbride's Institution."

In thus rapidly alluding to former medical officers of this hospital, it must not be supposed that I fail to recognize the beacon-lights of the profession now existing in its present staff. Time has not yet ripened their harvest, which, when gathered by some future historian, will doubtless exhibit its own heavy crop of brilliant thoughts and acts.

Nor is it wished invidiously to compare the present duties and labors of our residents with those of a former period. On the contrary, if any good is to be derived from this reference to the past practice of the house, it should be drawn from the fact that it exhibits the wonderful opportunities for gaining a sound practical education, offered then (as now in a modified form) to all who were fortunate enough to receive the appointment of resident physician in so large and varied a hospital, and should impress each one with the responsibility that rests upon him to make good use of his faculties for study from nature at the bedside, remembering that idleness or neglect of duty is not only a wrong to those whose lives may hereafter be intrusted to his care, but is also a wrong to his professional brethren, by depriving them of facts which it is his place to collect and publish. The professional reputation of more than one now prominent physician commenced in the report of cases and comments thereon, made in his early medical life while a resident of this hospital.

A peculiarity in the education of the residents, furnished by this house, that is daily becoming more apparent, is seen in the wide sphere presented for observation and study. The growth of specialties and the limitation of medical attendance on separate organs, as if the human body were not an entity, with each part dependent on the proper action of its fellow-organ, is, it may be feared, not likely to augment the class usually known as general practitioners, or the highly educated and accomplished physician of extended and varied experience, who recognizes the human frame as a compound organism formed of parts mutually connected by vital affinity.

Such practitioners as the "family doctor," a class much underrated by conceited specialists, met nearly all the medi-

cal wants of a family, whether in attendance on the mother in her confinement, or the father with an injured limb or a hernia, or the children in the diseases of childhood. These men became familiar with and readily recognized the physical peculiarities or idiosyncrasies of each member of a family, and, not unfrequently, after years of faithful service, gave their professional skill for the relief of those children's children. When under extraordinary circumstances further assistance might be demanded, as in delicate operations requiring peculiar manual dexterity, the family physician has now the opportunity of gaining it by consultation with those connected with special hospitals, a class that did not generally exist fifty years since. One great advantage to be derived from a medical residence in the Pennsylvania Hospital is to be found in the fact that it *is* a *general* hospital, and has no specialties, and that the mind of the youthful resident physician is liberalized and enlarged by studying *every* variety of disease or injury, and nearly *every* possible suggestion of varied treatment eliminated by the active brains and extended experience of the attending physician or surgeon.

Reference has just been made to the fact that much of the subsequent reputation and advancement in practice of those who have been the resident physicians in this hospital originated from their observation and reports of the curious and instructive cases presented in its wards. Among numerous marked examples of this, I cite the labors of Gerhard and Stewardson, two former residents, who pointed out the difference between typhoid and typhus, or of yellow and remittent fevers. Until within a little over fifty years, typhoid fever was *not* recognized in the United States, and it was not until Gerhard, profiting by the instruction of Louis and Chomel in Paris, returned to Philadelphia and became a resident physician in this house, that beginning a series of observations here, and conducting them subsequently in the Blockley Almshouse (which he published in the *American Journal of the Medical Sciences** and the *Philadelphia Medical Examiner* in 1835 to 1839†), our profession recognized and judiciously treated this formidable fever. In referring to this fact in his extended treatise on the practice of medicine, the late Professor George B. Wood states‡ "that the profession is much indebted to Dr. Gerhard for the means of accurately diagnosing typhoid from typhus fever; this being the result of his careful post-mortem examinations, and no less careful observations during life, furnishing a positive proof of an essential difference between the two diseases which Louis himself had previously been disposed to consider identical;" and these differences were subsequently confirmed by other observers. Another resident, F. W. Sargent, showed§ the occasional existence of the "taches rouges" or rose-colored spots in typhus fever all over the body, but mingled with its characteristic petechiæ.

Stewardson, in studying forty-three cases of remittent fever in this house from 1838 to 1841, showed‖ the diagnostic signs of remittent and pernicious intermittent from typhoid; Gerhard having previously claimed that *our* typhoid is not identical with that described by Louis, and that "he had a sufficient number of observations to prove that it is entirely distinct from the autumnal fevers of this country." In 1842 Dr. Reynell Coates, a resident of 1819–1823, now living, reported¶ Barton's bran dressing for compound fractures of the leg,—a dressing not as yet surpassed for such cases by any modern appliance to keep out microbes. Whilst Gerhard was occupied in the medical wards, Kirkbride was engaged and reported in the same journal in 1835** numerous cases of varied interest in the surgical and obstetrical wards, as strangulated congenital inguinal hernia cured by Barton, by making the testis adhere to and fill up the inguinal canal; tardy union in a fracture, cured by friction of the ends of the broken bone; the absorption of the callus from too early exercise after the fracture; injury of the abdomen creating peritonitis; case of rupture of liver and kidney; puerperal phlebitis; temporary loss of vision cured by leeches and a blister to the temple; luxation of a humerus reduced by the application of pulleys for thirty minutes and

free venesection. There was no anæsthetic then, and I have often seen the pulleys thus used and made fast to posts which stood for many years in the rotunda, these being kept there only for use in the reduction of dislocations. Another case he reported was a gunshot wound of the thorax, that was bled f℥xxx, and took one-eighth of a grain of tartarized antimony every hour; was bled on the second day f℥xxx, cupped freely, and purged with salts and tartar emetic; bled on the third day f℥xx, and lived until the seventh day, when the autopsy showed pleurisy and the wad of the pistol and some particles of clothing embedded in the substance of the lung, the irritation of which could not be removed even by such bleedings. I will only mention two other important acts of residents, viz., the suggestion in 1827 by George Fox, then a resident, of his bandage for the treatment of fractured clavicle,*—a dressing that was the only one used for many years,—and the statistical table of Joshua M. Wallace† of all the fractures admitted into this house from 1751 to 1800, which labor he performed in addition to his duty as a resident.

I will not longer tax your patience and keep you from the bright remarks to be made by others who are present, by further details of the varied labors and industry of the residents of this distant period. Most of them have gone to their rest, but the influence of their good deeds remains for the benefit of their successors. Suffice it now to say that I have made but a partial enumeration of the clinical advances made by attending officers and residents and again disseminated throughout the world through the varied classes of pupils that followed them in the rotunda of this house. Here Gerhard so taught auscultation and percussion as made many an excellent auscultator. Here Barton made surgical dressings with a neatness and picturesque effect that induced one young resident to make such constant practice and study as subsequently led to his efforts as a teacher of Minor Surgery and Bandaging, and caused it to become a subject of didactic instruction in every medical college in this country. The young graduate no longer enters the wards of a hospital, as he did, to be mortified at finding that an old surgical nurse can apply a bandage, make a poultice, or introduce a catheter with greater facility and more practical skill than is possessed by him, who holds a diploma creating him a doctor, or learned man. Prior to the year 1855 no such instruction was furnished in any of our colleges. *Now* it is taught everywhere, and there has been recently established in New York City a professorship of this important part of a young surgeon's education.

The credit of establishing this useful instruction may, I distinctly state, be justly assigned to the ideas first received in this house, and subsequently developed under the stimulus of the artistic dressings of a surgeon of the Pennsylvania Hospital, who created for himself a lasting professional monument in the suggestion of the beautiful and judicious dressing for fracture of the jaws known as "Barton's Bandage."

Such, gentlemen, are a few of the reminiscences of a former resident of the Pennsylvania Hospital, that present evidence of its value as a clinical school.

Perhaps some of you will be disposed to regard these recollections as those of an old fogy; but, if so, please remember that he will be extremely gratified to learn that there are those among the residents of the present time who can surpass by talent and industry the labors of those to whom he has alluded,—men who were instructed in their professional duties and sentiments by such teachers as Barton, Randolph, Norris, and Wood; not to overlook such distinguished obstetricians as Hugh L. Hodge and Charles D. Meigs, who often cured neuralgia of the ovaries without spaying the patient.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY HOSPITAL.

SERVICE OF D. HAYES AGNEW, M.D., LL.D.,

Professor of Surgery in the University of Pennsylvania, etc.

(Reported by CHARLES BAUM, M.D.)

PAINFUL MUSCULAR SPASM TREATED BY EXCISION OF PORTION OF THE NERVE-TRUNK.

GENTLEMEN,—Some of you will recognize this patient as the man from whom a portion of the right spinal accessory nerve was excised, towards the close of my lecture one week ago, for a nervous affection, the history of which is briefly

as follows. About one year ago he began to experience lateral twitching of the head, with choreic movements of the muscles of the right side of the neck, the sterno-cleido-mastoid and the trapezius being principally involved. This was accompanied by pain, which gradually increased in intensity so that frequent injections of morphine, hypodermically, had been required for relief. For a short time he was in the medical ward of this hospital, under the treatment of Professor H. C. Wood. His head was drawn to the right side. Frequent spasmodic rotary motions of the head occurred, and the pain became almost unendurable. Even slight pressure along the right sterno-cleido-mastoid muscle developed several points of exquisite tenderness and provoked the movements of the head. Being guided by the results of pressure, and not by the position of the head, an incision was made along the posterior border of the right sterno-cleido-mastoid muscle, beginning a little below the tip of the mastoid process of the temporal bone and extending about two and a half inches. After dividing the superficial structures, the posterior border of the muscle was observed: this muscle was then turned towards the median line of the neck, thus exposing the spinal accessory nerve, which principally supplies the sterno-cleido-mastoid and trapezius muscles, and from it about one-half inch of its trunk was excised.

Immediately after the operation all pain and movements ceased, and the patient slept well without an anodyne. Thus far only one twitch of momentary duration has recurred. At present pressure does not produce pain or motion.

In regard to prognosis, I may say if the irritation has been peripheral the result will be permanent; if central in its origin, the symptoms will return when the nerve-extremities unite. Much may also be accomplished by judicious general treatment.

MORBID GROWTH REMOVED FROM THE BLADDER.

The next patient for operation has been sent to the hospital from Washington, District of Columbia, by my friend Dr. Yarrow.

For fifteen years this middle-aged man has been annoyed by frequent micturition, pain in the back and bladder, and for one year by bloody urine. At times the blood has been mixed with the urine, and again at other times has appeared only at the close of micturition. Rest in bed and appropriate treatment have always afforded considerable relief, but any exercise would increase both the pain and flow of blood. Gradually he has grown nervous and anæmic. His urine flows without force, and the stream is frequently interrupted. After complete dilatation of a urethral stricture, several months ago, his symptoms were slightly relieved for a short time. Suspecting some growth within the bladder, Dr. Yarrow introduced an instrument and brought away a fragment of tissue, which proved to be papillomatous when examined under the microscope.

Frequent micturition, as a symptom, may accompany disease in any portion of the genito-urinary tract. The duration of the symptoms without the appearance of œdema, either of the face or the extremities, and the absence of tube-casts in the urine, will exclude Bright's disease of the kidney. As renal surgery recently has made such great strides, every surgeon is on the alert to detect renal disease demanding an operation. In this patient renal colic, which might indicate a calculus, has not occurred. Percussion and palpation of the abdomen do not reveal a displaced kidney or any enlargement from hydronephrosis, pyelonephrosis, or neoplasm. Neither irritative fever, the result of acute inflammations, nor hectic fever, due to the formation of pus, has occurred. There is a small amount of muco-purulent secretion in the urine, but far less than that which occurs in acute and chronic cystitis. In fact, the only constitutional symptoms manifested are those resulting from loss of blood and pain. Pain at the orifice of the urethra and frequently down the thighs is a symptom of vesical calculus; but the sensation in these parts is normal, while the sound does not detect a stone. The prostate body is not tender or swollen, and, with the absence of rational signs, excludes prostatic diseases.

In this case bloody urine has been a prominent symptom. Even a small quantity of blood imparts a smoky or mahogany-brown color to this secretion. In urine containing blood, more or less albumen will always be detected. The blood may escape from the kidneys, ureters, bladder, or urethra.

Blood from a kidney is generally uni-

formly diffused through the urine, because it enters the bladder drop by drop. The causes of kidney-hemorrhage are many, such as changes in the composition of the blood, injuries, inflammation, ulceration, neoplasms, and parasites. Hemorrhage from a ureter is very rare, except from the presence of a calculus, while the coagula formed are long, slender, and worm-like when floated in water. Bleeding from the prostate results from inflammation and hypertrophy, the clots being fusiform; that from the urethra is also generally occasioned by inflammation, stricture, or an impacted foreign body, while the clots are cylindrical in shape. Lastly, the blood may come from the bladder itself, and be the result of inflammation, injury, calculus, parasites, or neoplasms. Coagula from the bladder may resemble coffee-grounds, due to their being partially dissolved in the urine, or they may be flat and irregular in outline. In urethral hemorrhage the first portion of urine voided usually contains blood, while the last portion is clear. The reverse is the rule in vesical calculus, the blood appearing at the close of micturition; for at this stage of the act the contracting bladder grasps the rough calculus, which inflicts minute wounds in the mucous membrane.

In this patient, the clinical history and the physical examination would lead us to suspect some vesical neoplasm.

Morbid growths of the bladder are both benign and malignant. Of the benign growths adenomata are rarely observed, while the fibromata are usually found, especially the villous form, or so-called papilloma. In considering malignant disease, tubercle may be looked for only in conjunction with general tuberculosis; sarcoma is seldom observed, while the epithelial variety of carcinoma is the most common of its class.

I now propose to open the bladder by perineal section and make a digital exploration of its inner surface. The patient is placed in the lithotomy position. As the urine was recently voided, about six fluid-ounces of water containing mercuric chloride (1 to 2000) will be injected into the bladder. A grooved staff will be introduced and kept well against the pubic arch. The incision, about two inches in length, ending three-fourths of an inch above the anus, will be made in the median line, the raphé. After opening the membranous portion of the urethra, the staff is to be removed and a blunt gorget used to dilate the wound, to be followed by the finger. Sometimes the prostate gland is cut and the finger alone used to dilate the parts. If a growth is discovered, a serrated forceps will be used to separate it from the bladder by crushing its attachment.

Making supra-pubic pressure, every portion of the mucous surface of the bladder is brought in contact with my finger. The upper part is perfectly smooth, on the right and left sides low down there is slight thickening of the mucous membrane, and at the base a growth almost sessile in attachment is felt.

[A villous fibroma or papilloma, about the size of a walnut, was removed.]

The after-treatment will consist in perfect quiet, liquid diet, and opium if necessary.

TRANSLATIONS.

Herpes Zoster and Paralysis of Motor Nerves.—The combination, as yet not very frequently observed, of herpes zoster (the expression of disease affecting sensory or trophic fibres) with the paralysis of motor nerves can be traced back in one series of cases to a central lesion, in which the process from the trophic nerve-tracts has encroached upon the motor centres, or the reverse.

In another series of cases a peripheral mixed nerve is concerned. Besides these, however, there are still cases which can be referred to neither of these sources, and in which only the most external periphery of the nerve is affected. To this class belong those cases of herpes zoster of the face or the neck which occur in connection with paralysis of the facial nerve. To seven such cases collected by P. Strübing (*Deutsches Archiv für Klin. Med.*, Bd. 37, 1885) from medical literature, he adds one under his own observation. A man 52 years of age was exposed to the action of a cold draught of wind upon his face. A few hours later a neuralgia developed upon the left side of his face, which was followed by herpes, and a few days later by a paralysis of all the facial branches of the left facial nerve and the left chorda tympani.

As regards the question of the connection here between the zoster and the paral-

ysis, it cannot be set down as purely accidental. Reflex paralysis can scarcely be taken into consideration, because the facial paralysis presented the characters throughout of a peripheral and not of a central affection. Quite as unlikely, according to the reporter, could the view of Eulenberg be adopted, that in facial paralysis an eruption of herpes may be induced by irritation of the trophic fibres in the facial nerve (which possibly come originally from the vagus), because one and the same morbid agency would then have to cause irritation of the trophic part of the nerve and paralysis of the motor portion of the nerve. The connection in this and similar cases may be, with the greatest probability, sought for in some inflammatory process extending through the connecting fibres from one nerve to the other, so that a peripheral affection of a sensory nerve (which leads to herpes) will produce a peripheral facial paralysis, and *vice versa*. In other cases the connection may be so clear that one and the same injury (such as exposure to cold) may affect both the trigeminus and the peripheral branches of the facial, and develop herpes zoster and paralysis coincidently.—*Deutsche Medicinische Zeitung*, December.

Hypnotism during Parturition.—In the *Wiener Medizinische Wochenschrift* (No. 45), Dr. E. Pritzel, assistant to Prof. Karl Braun, reports a case of childbirth during hypnotism, probably the first of the kind on record.

The patient, single, 26 years of age, was admitted to the obstetrical wards of Prof. Braun in the eighth month of pregnancy. She had always menstruated regularly from her fourteenth year up to January of last year; since then her health had been good, and she had been entirely free from the nervous manifestations so common during pregnancy.

Upon examination, it was found that she was readily thrown into a hypnotic state by holding a thermometer-bulb before her eyes for a few moments: she became unconscious and insensible to all irritations, while her color, pulse, and pupillary reactions remained unaffected. At the end of a quarter of an hour or half an hour, the patient was aroused by long and continued irritation, shaking the body, blowing upon the cornea, slapping the breast with cold wet cloths, etc. After revival, she declared that she felt well after each experiment, but it was noticed that it was usually followed by a deep, but natural, sleep.

Labor set in October 30, and during the first stage she was restless and unmanageable. Cramps in the limbs and intensity of the pains during the second stage suggested a narcotic or the induction of artificial hypnotism. The latter expedient was adopted, and with entire success. She became unconscious and insensible. It was found that, instead of decreasing in force, the uterine contractions became more energetic, and were aided by the abdominal muscles. While the patient was entirely insensible, it was still noticed that she bent the left forearm as if cramp were present, and there was considerable stiffness in the left leg; the right side of the body was unaffected. Between the pains she lay motionless, as if asleep. A well-developed female child was born, which cried lustily; the placenta was expelled, under the influence of abdominal pressure, in three-quarters of an hour. The patient was wakened by holding ammonia to her nose and shaking her, after unconsciousness lasting an hour and a quarter. The confinement was in every other respect strictly physiological. In two other cases from the same clinic the method was also successful, although to a less marked degree.

Cocaine for Sea-Sickness.—Dr. W. Otto, physician upon a steamer between Bremen and New York, used cocaine hydrochlorate with much satisfaction in the treatment of sea-sickness during last summer. The dose for an adult was one-fourth to one-third of a grain, given for a single dose or three times a day. While these doses were well borne, larger ones did not control the vomiting; the remedy was usually given in ten-per-cent. solution by the mouth. The patients were directed during the first day to maintain a recumbent posture. Vomiting and nausea quickly disappeared, and sleep followed so uniformly that some thought they were taking morphine. The most successful cases were those of pregnant women, who generally suffer extremely with sea-sickness. There were a few cases which remained sea-sick, in spite of the cocaine, until the end of the voyage.—*Berliner Klin. Wochenschrift*, October 26, 1885.

EDITORIAL.

SOME MEDICAL PROBLEMS OF THE DAY.

MEDICINE is a progressive and therefore an imperfect science, but each step in advance provides a vantage-ground from which new fields may be explored. "Science," as the thought is gracefully expressed by Holmes, "is the topography of ignorance. From a few elevated points we triangulate vast spaces enclosing infinite unknown details." New responsibilities, new problems for solution, as the rule, grow out of each addition to our knowledge of pathology and therapeutics, and it is only exceptionally that some great discovery or new application, like the discovery of anæsthesia, vaccination, or the ligation of arteries, appears upon the scene to revolutionize medical practice.

Upon reviewing the work of last year in the medical world, we observe some errors committed, but more corrected, and many contributions to the common fund of knowledge which are apparently both new and true; while, if the assertion of Pasteur that the cure for hydrophobia has been definitely found can be accepted fully and literally, the year 1885 has been marked by at least one great medical discovery.

In general medicine, the study of bacteriology has lately led to improvements in technique rather than to new achievements in the field of the relation of microbes to morbid processes. Indeed, attention now seems to be particularly directed towards the peculiar condition of protoplasm in the living human body by which it is rendered a congenial host for the reception and cultivation of disease-germs. The question now is, What is the *quid intus* which must be present in the organism in order to produce a favorable soil for the development of germs? In what does vulnerability or susceptibility consist, how does it arise, and how may it be destroyed? What relation does such special susceptibility bear to the clinical picture which we call disease? Representing the morbid combination by ten units, will the susceptibility represent two or three and the germ eight or seven, or *vice versa?* or, in some cases, may the predisposition in reality be the disease, and the germ (so called) an incident or accident in its course? These problems are now before the profession for solution.

The problem of reducing or destroying susceptibility in the human organism by inoculation with a mitigated virus—so successful in variola—has not made much progress, Pasteur's experiments excepted. Ferran's protective inoculations against cholera in Spain were successful, it is believed, in the primary object for which they were practised (*i.e.*, providing for Dr. Ferran's family), but there is no reliable evidence to show that they possessed any scientific value whatever; on the contrary, they have caused erysipelas, septicæmia, ulcerations requiring amputation of limbs, and, in a few instances, death. The exposure of Ferran by the French Commission has thrown some discredit upon protective inoculation for epidemic cholera, but the prophylactic inoculations for yellow fever have been continued, and the reports from Freire and Carmona positively claim highly successful results.

The announcement of Pasteur to the French Academy last October that he had solved the problem of the prevention of hydrophobia by means of hypodermic injections of morbid material has attracted much attention to the subject, and, owing to the highly-flavored accounts published in the daily papers, many persons who have been bitten by dogs believed to be mad have been sent to him to be treated by his method. It is stated that he has in view the

establishment of an institution in Paris for the treatment of such cases. Similar institutions have been also projected in London, New York, St. Louis, and elsewhere.

With regard to this matter, it is well to bear in mind that rabies canina is a rare disease in this country, and that only comparatively few persons annually are bitten by dogs that are really mad. Of those bitten, authorities state that fully fifty per cent. will escape having the disease, even without any treatment whatever; in the others, immediate and thorough cauterization of the wound is pronounced an almost infallible means of preventing the future development of the disease. When the precaution of thorough cauterization has been taken, especially if combined with excision, as recommended by Gross, it is believed that the danger to be apprehended from subsequent hydrophobia is slight, and the necessity for the establishment of institutions for Pasteurization, therefore, infinitely small. Moreover, one of his patients, the papers state, has since died with hydrophobia, although the inoculation had been practised. Here the failure was attributed to the lapse of time between the bite and the hypodermic puncture,—thirty-five days having been rather arbitrarily set as the limit beyond which the treatment is useless. Before this treatment is generally adopted, the question must be considered, What is the danger from the inoculations themselves? Erysipelas and septicæmia may be not too heavy a price to pay for immunity from such a dread and fatal disease, but is there any possibility of the inoculation of the *materies morbi* giving rise to the very disease which the bitten one is most anxious to avoid? We cannot help regarding this new development of isopathy with some mistrust, at least until it rests upon a more secure foundation. In the mean time, we can but deprecate the evident popular craze upon the subject, which originated in premature and partial accounts in the public press.

Turning to subjects more directly concerned with pathology, we find that views advanced last year by Dr. Ord, in his presidential address before the London Medical Society, on the origin of pyrexia, are new and important. During the building up of complex tissues there is a loss of sensible heat; and it was held by Dr. Ord that, this constructive process being disturbed in fever, the heat is not locked up, as it should be, but continues active, and becomes added to the heat produced by excessive tissue-combustion. Fever-heat, then, is the joint result of interference, through disturbed innervation, both in the constructive and in the destructive metabolic processes. That the undue liberation of heat at the surface of the body is dependent upon some disorder of the nerve-centres has not been definitely established, and, for the present at least, we must regard fever as a disorder of protoplasm.

In surgery, among the many topics which might be considered, we may mention, as a positive evidence of progress, the publication by Lawson Tait of one hundred and twelve consecutive cases of laparotomy for operation or exploration, without a single death. The transplantation of the eye of a rabbit or a dog into a man's orbit for cosmetic purposes has been performed five times during the year, according to M. Terrier, who reported them to the French Academy of Medicine. In but one case, however, was the experiment successful, and that was performed by an American, Dr. Bradford, of Boston, who introduced a rabbit's eye into the orbit of a sailor thirty-five years of age, upon whom enucleation of the eye had just been practised.

Brown-Séquard announced to the Academy of Sciences that he had succeeded in causing general analgesia in man by introducing carbonic acid gas towards the end of inspiration, so as to act directly upon the larynx. The inhalations, if kept up for

twenty or more minutes, he stated, would produce analgesia and relief from pains, however induced, extending to forty or even to forty-eight hours. In connection with this, we think it is important to call attention to the employment of hypnotism as a substitute for anæsthetics in obstetrics, as in a case reported in another column.

Dujardin-Beaumetz adds to the list a new hypnotic, which, in recognition of its decided effects, he proposes to call "hypnone." It was discovered by Dr. Bardet and himself, and belongs to the aromatic series; it is a mixed acetone or aceto-phenone (phenyl-methyl-acetone). It is said to possess decided hypnotic properties in doses of from two to four drops to adult patients. It is not miscible with water, but may be given in capsules with glycerin. Injected hypodermically, it causes insensibility, followed by coma and death.

The preparations for the International Medical Congress to be held in Washington in 1887 have made decided progress. Within the last few months an independent executive committee was formed, and the necessary preliminary arrangements have been begun in a manner to inspire confidence in the present management of the affairs of the Congress, the prospects for which are decidedly better than they were one year ago.

The interest in sanitary matters and public health in the public mind has been maintained during the past year, and shows a healthy growth. In accomplishing this desirable end the American Public Health Association and the various State and County Medical Societies have contributed to a very great degree. Among the indications of progress may be mentioned the establishment of a State Board of Health in Pennsylvania, chiefly through the persistent efforts of the State Medical Society. It is hoped that public attention will now be directed to the great need of a State Board of Medical Examiners, and also of a change in our coroner system.

*

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

FOR the time being the country is absorbed in an election-struggle, and country doctors complain that they are doing little or nothing: betwixt the election and the depressed condition of agriculture, people do not want medical attendance. The medical candidates have met with rival fortune. Dr. Balthazar Foster, of Birmingham, has been successful as the Liberal candidate for Chester; Dr. Danford Thomas has fallen after a game struggle for Islington; Sir W. Guyer Hunter gained a metropolitan seat; Dr. Watney failed to secure Deptford; and Dr. Alfred Carpenter, who seemed a strong candidate for one of the divisions of Surrey, was defeated; while Prof. Erichsen is waiting the reply of the graduates of Edinburgh and St. Andrew's Universities, as did Dr. Gordon Hogg, in vain, for the opinion of the electors of Ealing in West Middlesex. The editor of the *British Medical Journal* has not succeeded in winning over the Radicals in the East End, and had a bad fall, finding comparatively few supporters. The danger of an even balance of parties, so as to put the Irish party into power and prevent all legislation until they were disposed of in some way, has largely passed away. Even for the brief time when it was impending, a curious trait in the Anglo-Saxon character manifested itself,—viz., their utter intolerance of any attempt on the part of an inferior race to coerce them. The Anglo-Saxon has been a comparatively merciful ruler towards subject races so long as they recognized his superiority and authority. But any attempt to cast off his yoke has been met by a stern, uncompromising resistance and a further fastening of the fetters. This was markedly seen in the behavior of the English at the Indian mutiny. It was stamped out effectually and promptly. During the past few days, when it seemed that Mr. Parnell, "the uncrowned king," was going to be master of the situation, the same spirit showed itself everywhere, and every one was talking of what must be done in order that the legislative arm of the nation should not be paralyzed; for, with a neat balance of power, neither side could rule except at Mr. Parnell's will. One thing was certain with all, and that was that Ireland should not rule England. When King Charles the First, in sore straits, intrigued to bring over so many Irish kerns to ravage England, the feeling manifested was strong and led to further alienation of the people from their king. So it was again. And even in the strife of parties and in the midst of a keen political contest, unanimity prevailed on this topic, and by common consent men of all parties were agreed to take measures against such a catastrophe. How-

ever, this danger, lately seeming so threatening, is already a matter of the past.

Within the medical profession, the two matters of gossip and speculation are: first, the matter of a university degree for London medical students, which is becoming a burning question; and, secondly, what is going to be done to that unworthy member of our profession who figured in the trial of which something was said in my last letter. As to the medical degree, a variety of propositions seem to be in the air. Of the great basal matter, the desirability of a degree on terms more reasonable than the existing "M.D. London," all concerned agree,—unless it be some of the present graduates of the London University. To put it broadly, it would appear that the position is somewhat like this: (1) a union of the two Royal colleges, which are non-teaching corporations and merely examining bodies; and (2) the formation of a teaching university. A third proposition has just emanated from University College in an inchoate form, the drift of which seems to be to convert University College into a teaching university. The exponent of this last device was Professor Ray Lankester, F.R.S., to whom has just been awarded the Royal medal of the Royal Society, in recognition of his important researches for a number of years in embryology and other biological and zoological subjects. The matter is being taken up in earnest, and there is every prospect that a solution will sooner or later be found; but it cannot be expected that the resultant decision will be acceptable to all parties. The rivalries and jealousies of the numerous schools, the lethargy of the two great corporations, are two great stumbling-blocks in the way of any and every conclusion. The agitation will have the effect of adding to the growing sense among the profession at large that the interests of students and of practitioners are, in the present state of matters (as in the past), utterly subordinated to those of the colleges.

The other is a painful matter, as affecting the position of the profession morally and socially. A medical man is largely a privileged man, who enters into the very *sanctum sanctorum* of families. The greater the confidence reposed in him, the greater should be his sense of responsibility and his care not to presume upon nor abuse that confidence. In my last I gave some account of the curious proceedings of an evening metropolitan newspaper in reference to the abuse of young girls. The judge's summing up ran closely upon the lines laid down in that letter, and the eccentric editor has now for some time been a prisoner in one of Her Majesty's jails. The judge made some strong comments upon the conduct of the physician who consented to take part in such questionable proceedings. So strong were they that all wondered what steps would be taken in the matter by the ruling powers of the medical world. The judge said,—

"Dr. Heywood Smith thought fit to examine this child after subjecting her to chloroform. Dr. Smith had been told that the child had been bought for immoral purposes; that an examination had been made by Madam Mowrey; that she had been taken to a brothel; and there was no doubt he had been told everything that had happened. Notwithstanding this, and having, I presume, the knowledge that neither Mr. Booth nor Mr. Stead had any right to deal with the child, he had the child sent to No. 27 Nottingham Place; went there himself at between two and three o'clock in the morning; had chloroform administered; and then examined the child. I do not hesitate to say that anything more discreditable to a medical man I cannot imagine; and I grieve to think that anybody belonging to that great profession to which Dr. Heywood Smith belonged should do such discredit to it. I say that advisedly, after a careful consideration of the circumstances."

The midwife who examined the girl without administering chloroform got six months' imprisonment. What happened to the other individual who also indecently assaulted the poor child? The Council of the British Gynæcological Society accepted his resignation of the post of Honorary Secretary, while admitting the valuable services he had rendered to it. The only other step was this: at a recent meeting of the General Medical Council, "in reply to a question addressed him on Thursday by Dr. I. H. Watson, the President of the Council said the Royal College of Physicians of London had under consideration the conduct of a registered medical practitioner, a member of the College, whose professional conduct had recently been severely censured by one of the English judges, and that it would rest with the Branch Council to decide what action should be taken in reference to the case, after the decision of the College of Physicians has transpired." (*Medical Press and Circular.*)

A fortnight has now elapsed, and the College of Physicians has not yet come to any conclusion: so that the Branch Council are still waiting patiently the judgment which is to give direction to their own action. Here the matter stands; and yet the College proposes to guarantee the conduct of its Fellows and members. There are two or three weeks' washing of dirty linen on hand already in Pall Mall. There stand over several instances of unbrotherly conduct on the part of its Fellows towards each other, and one of members towards each other; but in these cases there have been no opinions expressed by a judge to guide the College to a conclusion. Now they are face to face with something more than a scandal, and the public, as well as the profession, await their verdict. That a

body which has studiously practised shuffling as its line of conduct, and has evaded every occasion for a decision, while its own procedures have been marked by what may be called clandestineness, should feel very uncomfortable when called upon for decision under the fierce light of public interest in the question, is conceivable enough. Where infirmity of purpose and procrastination rule, it is hard to be put to a decisive conclusion before an impatient public. One can understand, if one cannot sympathize with, their dismay and hesitation. Here is the Branch Council of the medical parliament and judicial bench waiting upon their action, and evasion is impossible,—at least, one would think so; but, however, time will tell. It will be a novel spectacle to see the Royal College of Physicians of London taking up a distinct attitude on such a question; and its decision will come with much the same sense of strangeness as we would experience were an eclipse of the sun or moon to occur which has not been predicted.

In a paper read before the Medical Society of London recently, the writer expounded his views of gout. He pointed to the fact that, when kidneys first appear in the animal world, the form of excretion as regards nitrogenized waste is uric acid. Uric acid is found with animals with a three-chambered heart and a solid urine,—viz., birds and reptiles. When the mammalia appear, we find a four-chambered heart and a fluid urine, with the soluble urea as the form of nitrogenized excretion. Certainly a trace of uric acid remains in the urine of many mammals. When the human liver becomes impaired, depraved, or degraded, it fails in the (practically) complete conversion of nitrogenized waste into urea, and falls back upon or reverts to the primitive urinary product of the lower animals,—viz., uric acid. Gout, then, is (in its broadest sense) liver-reversion,—the formation of primitive urinary products by a mammalian liver. This definition throws a ray of luminous light upon the genesis of gout. Of the causal associations of gout and their relations to good living (in the present or in the past) the world has long been agreed. One man inherits gout, and has to practise the greatest self-denial in meat and drink throughout life in order to ward off the visits of his hereditary foe. But then it will be found, on investigation, that the individual is the product of a family which for generations has kept a table, and that a long-sustained struggle with an excess of nitrogenized food, lasting over several lives, has impaired the functional efficiency of the liver. On the other hand, the humbly-born alderman, whose liver is in all its integrity, can eat and drink to old age without making the acquaintance of the gout, sometimes, indeed, escaping himself scot-free, to hand down a tendency to uric-acid formation—along with his savings—to his descendants. This liver-reversion is intelligible, and helps us practically to deal with gout. It is quite clear that the first step is to reduce the demand upon the inefficient viscus. Physiological rest is of the greatest utility in enabling an impaired organ to regain its waning capacity. Consequently, it is well to cut down the amount of albuminoids in the dietary for a beginning. About that step there can exist no two opinions. Then as to the utility of uric-acid solvents, as lithia and potash, there is not much doubt. Dr. Garrod put us a good step forward when he showed that the comparatively insoluble uric acid and urates were readily soluble in the presence of these two bases; and in many cases, no doubt, it is a convenient method of dealing with uric acid so to wash it out of the system, daily doses of uric-acid solvents, well diluted, being taken to meet the daily formation of the uric acid. This is a great step forward, doubtless; but experience is beginning to tell us in unmistakable accents that something more is possible and practicable in addition to this. The liver is lowered as to its functional vigor, and insoluble uric acid is being formed rather than the soluble urea. That is one side-piece of the ladder of hypothesis. The other is that we are in possession of certain agents which are hepatic stimulants, and which have a special effect upon the liver. The group consists of sundry vegetables, of which the best-known are taraxacum, ipecacuanha, rhubarb, aloes, euonymin, iridin, and baptisin. Not only in true bilious conditions (where their value is generally conceded), but in lithæmic or gouty states, these agents possess a useful action. By their influence upon the liver they seem to have an elevating effect upon the processes by which waste and surplus nitrogenized matter are sent downward as products cast out of the body as urinary excreta. For some years now it has been the practice of the writer in cases of liver-inadequacy (whether cholæmia or lithæmia was the resultant malady) to combine these special hepatic stimuli with a general tonic like strychnia. Very satisfactory results have accrued from such a combination, especially where it is persisted in for some time. We all know how difficult it is to overcome a bad habit; and the organic viscera seem to acquire bad habits, as seen in chronic dyspepsia, the formation of renal calculi, recurrent liver-disturbances of the bilious nature, recurrent abortions in certain uteri, and the return of gouty states. Time, then, is an essential element in the treatment of such a vicious habit as the tendency to form uric acid. But by physiological rest as regards the metabolism of albuminoids—*i.e.*, lessened work and increased functional capacity, the effect of the hepatic stimuli—this morbid tendency can be to a great extent overcome. In one case which has been very carefully watched, where there

was a decided tendency to the formation of uric acid and a chronic gouty condition, and, after standing twenty-four hours, the pale urine had a pinkish hue, with a distinct deposit of cayenne, the change under the plan advocated above has been very marked. The urine is less in bulk, is of normal hue and odor when passed, and, on standing, no uric-acid deposit is found; while at the same time the general condition is very satisfactory. "One swallow does not make a summer," and, if the case stood alone and unsupported, it would possess but little clinical value. But when it is borne out by a series of allied cases it has a measurable value.

It is not perhaps very generally known that persons of thin flank do not bear alkalies well. In spare gouty persons (as indeed in spare bilious persons) alkalies are not well borne, as a rule. In such cases it is well to resort to hepatic stimuli rather than to uric-acid solvents: the alkaline lithia and potash. Even some stout and stalwart persons cannot tolerate potash. Lithia is less depressant than potash, but still it is too lowering for some persons. In such cases the line advocated above will give more satisfactory results. Phosphate of soda is an hepatic stimulant, and, where a mineral salt is indicated, is often most useful in liver-disturbances. In conditions of lithæmia and cholæmia it is of service, and it will often clear away the remains of jaundice in a satisfactory manner.

Therapeutic advances of recent years have taught us how we can act upon the nerve-centres of the heart when that organ is acting inefficiently. More recently we have discovered direct stimuli to the respiratory centres useful when the respiration is embarrassed. And now, it seems, we stand upon the threshold of acquaintance with remedial agents which can raise the tone of the liver when hepatic inadequacy is present and the system is suffering from the presence of toxic matters formed within itself.

J. Milner Fothergill, M.D.

PROCEEDINGS OF SOCIETIES.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held December 17, 1885, A. Jacobi, M.D., President, in the chair.

VAGINAL AND VULVAR ENTEROCELE.

Dr. T. Gaillard Thomas read a paper with this title, and said there were five varieties of hernia into the vagina and vulva: 1, cystocele, or hernia of the bladder; 2, rectocele, or hernia of the anterior wall of the rectum; 3, vaginal enterocele, or descent of a portion of the small intestine into the vagina; 4, pudendal enterocele, or descent of the small intestine into the labium majus, one or both sides; 5, perineal enterocele, or descent of the small intestine by protrusion through the perineum.

There might be exceptional cases going to form other varieties. Hernia of the bladder and anterior wall of the rectum were passed by with mere mention, and the author limited his remarks principally to descent of the intestine through the pelvic roof, with protrusion into the labium majus, vagina, or through the perineum. These forms of hernia were very generally ignored in systematic works on gynæcology, and indeed had received little attention in periodical literature. This was the more to be regretted because the condition, although a rare one, was very liable to lead to an erroneous diagnosis, and consequently to injurious treatment. While the cases were rare, they had been recognized a long time since, and a more graphic description of vaginal enterocele could not be given than that which had been given by Sir Astley Cooper in 1804.

Vaginal enterocele consisted in a descent of the intestines into the pelvic cavity either in front of or posterior to the broad ligament on one side. The descent was a little oblique, and most frequently occurred posteriorly. Usually the intestines alone descended into the protrusion, but sometimes they were accompanied by the omentum. Usually it was the small intestine. In vaginal hernia the parts were—first, the vaginal wall; second, the peritoneum; third, the intestine. The tumor might occur during labor and obstruct the progress of the fœtal head, and the obstetrician was liable hastily to infer that there was an ovarian or parovarian cyst with a long pedicle pushing down into the pelvis, and to plunge a trocar into it. If it occurred in a non-parturient woman he might undertake to remove the tumor, and find, to his horror, that he had cut away a portion of intestine. The condition might be brought on by the strains of labor, or by falls, or violent effort, etc. Strangulation seldom occurred. The symptoms consisted of difficulty in locomotion, pelvic tenesmus, dragging-down and colicky pains, tendency to constipation, and, in time, perhaps vomiting; if during parturition, there would be obstructed labor.

The physical signs of vaginal enterocele were a supple, soft, yielding tumor, decreasing on pressure, giving a sensation of gurgling to the finger if not heard by the ear, increasing on coughing and straining, yielding to pressure, and very generally reducible if the patient be placed in the knee-chest position and taxis practised.

Vaginal enterocele might be confounded with prolapsus of the vagina, uterus, bladder, or rectum, or a combination of these displacements; with vaginal cyst, parovarian cyst, or ovarian cyst, fibrous tumor low down in the pelvis, cold pelvic abscess, or marked

cases of tubal dropsy. But most cases presented striking features, and if one's attention were directed to the possible nature of the condition a mistake in diagnosis would not be likely to take place. The hernial tumors might show themselves in one of two ways: first, by brusque and sudden development, marked by alarming and decided symptoms; second, by slow development, with uneventful symptoms, the mere mechanical effects of the tumor finally attracting the attention of the patient. Rarely the cause of vaginal enterocele was a form of traumatism, causing the wall to give way.

In one case of vaginal enterocele, which Dr. Thomas saw in consultation with two physicians, one of the physicians, in order fully to satisfy himself of the correctness of the diagnosis, insisted upon introducing his entire hand into the vagina. In doing so he ruptured the vaginal wall at the site of the tumor. Dr. Thomas sewed up the rent, and the patient narrowly escaped death from acute peritonitis, and the physician was sued for malpractice. Another case had been recorded in which rupture of the vaginal wall of the tumor followed the use of tents. The rent was closed by silver suture, and the patient recovered.

There were two forms of pudendocele,—one being internal, commencing as in vaginal enterocele, but finally forming a protrusion of the labium, and the other the external or inguinal variety. The symptoms, which were almost pathognomonic of vulvar enterocele, were: 1, an airy feeling upon palpation; 2, gurgling upon replacement; 3, diminished tension in the dorsal decubitus; 4, diminution in bulk upon taxis; 5, resonance on percussion; 6, impulse transmitted to the hand on coughing; 7, intestinal pain, colicky in character.

Perineal hernia might affect either male or female. In the female it consisted in a descent of the intestine between the vagina and the rectum, the advance being posterior to the broad ligament, and continuing until the perineal muscles were forced apart and the gut, with its peritoneal envelope, was arrested by the skin. The sac lay between the vagina and the rectum.

All of these varieties of hernia were usually readily reduced, the reduction being greatly facilitated by the knee-chest position. In some rare cases strangulation occurred. Here the surgeon should cautiously open the sac and cut the constricting band by passing up a probe-pointed bistoury.

Dr. Thomas then related a remarkable case of extreme vaginal hernia which illustrated some unusual features.

The woman was 39 years of age. About six years ago she had noticed a lump in the vulva, and began to suffer from frequent micturition, pains in the back, nervousness, etc. The tumor gradually increased in size until it reached the middle of the right thigh. The patient became greatly emaciated and suffered extremely from the symptoms enumerated, and she was willing to undergo any treatment with a hope of obtaining relief. When by taxis she restored the tumor to the pelvic cavity, which could easily be done, she experienced such great difficulty in emptying the bladder and rectum that she was compelled to force it voluntarily out again. The tumor was of pinkish hue, and had the appearance of a huge cystocele. But this superficial impression was erroneous. After examining the tumor more carefully, and reducing it by taxis, Dr. Thomas concluded that it was without doubt a hernia of the intestine. It was utterly impossible to retain the tumor in its reduced position, for two reasons: first, because the pressure which it exerted against the bladder and rectum when within the body interfered with the function of these viscera so as to render the patient very uncomfortable; second, because of the great weight of the mass. Yet the condition of the patient urgently called for relief. Under these circumstances he suggested the following operation, which was eagerly accepted by the patient and her friends: to perform laparotomy; to have an assistant keep the tumor reduced by one hand in the vagina; empty the sac of its contents, seize it at its most dependent part, drag it up into the abdominal wound, fasten it there by suture, and sustain the heavy sac by two knitting-needles passed through it and lying flat upon the abdomen. Dr. Emmet and Dr. Bozeman confirmed the diagnosis and approved of the proposed operation. On opening the abdomen, his assistant pushed back the tumor, and the operator was surprised to find in the pelvis a soft fibrous tumor, which had been pushed up from below, on a level with the symphysis pubis, very movable, covered by peritoneum, disconnected with the uterus, and on careful examination proving to have no connection whatever with the bladder. The nature of the tumor could not be determined, but he decided to remove it. The sac was drained by a glass tube, and was fastened into the abdominal wound as had been proposed. The patient made a good recovery. It was now more than five weeks since the operation, and there had been no return of the hernia. Dr. Thomas, however, expressed some apprehensions as to the future. He thought the explanation of the case was that originally this very movable tumor entered the pelvic cavity behind the broad ligament on the right side, and with the weight of the intestines it pressed down upon the vagina, which it inverted. The contents of the sac were, then, the tumor and intestine. The microscopical examination was made by Dr. H. C. Coe, who said the structure was like that of an ordinary fibro-muscular tumor or a fibro-myoma of the uterus. It was not the bladder; it was not an ovarian cyst; it was not composed, at least

to any great extent, of inflammatory tissues. He submitted two theories as to the nature of the growth: first, that it was a local hypertrophy of the pelvic connective tissue; second, that it was a subperitoneal uterine fibroid which had become œdematous. He inclined to the former view, as did also Dr. Thomas.

Regarding treatment, there was but one variety of pudendal hernia—namely, inguinal—for which much could be done by mechanical appliances. Other varieties of hernia under consideration could only to a limited degree be relieved by such means. But it appeared to the author that the plan which he had partially carried out in the case reported promised more than any other yet brought forward.

Proposed changes in the constitution and by-laws were then read, and will be acted upon at the next meeting.

PHILADELPHIA ACADEMY OF SURGERY.

AT a stated meeting of the Philadelphia Academy of Surgery, held December 7, 1885, the President, Dr. D. Hayes Agnew, in the chair, several cases were reported, as follows:

CRUSH OF PELVIS AND COMPOUND FRACTURE OF LEG.

Dr. Nancrede: I desire to relate a case which is of considerable interest to myself and may be of some interest to the Academy. It is that of a man who was run over by a loaded wagon, one wheel traversing just above the crest of the ilium and running across the ramus of the left pubic bone. In some way the left foot became entangled, and he suffered from a compound comminuted fracture of both bones of the leg. There was simply a puncture of the soft parts, probably produced by one of the fragments. It was a compound fracture which would not *per se* have demanded amputation.

When I saw the man, three hours after the accident, he was suffering profoundly from shock. There was then a reasonable-sized effusion of blood just above the brim of the pelvis, extending into the scrotum and penis, but not involving the thigh. Scarpa's triangle was distinct and depressed. It seemed probable that the external iliac artery had received a severe injury. The limb was icy cold from Poupart's ligament all the way down. The arteries could not be detected anywhere below the brim of the pelvis. There was no hemorrhage from the compound fracture. The man was at this time in such a condition of shock that it was manifest that nothing could be done. He gave me the impression that he was suffering from concealed hemorrhage. My colleagues were, fortunately, in the hospital, and we examined him and came to the conclusion that the vessel was injured, but the man was not in a condition at the time for any operation, and that we would wait until reaction occurred. This did occur, and the temperature went up to 99°. I neglected to say that at the time of the examination the hæmatoma did not pulsate. When reaction supervened, bleeding again commenced, and when I saw the man the following day the whole thigh was tensely filled with blood. The effusion of blood beneath the peritoneum had extended from the median line about two inches above the pubes and the crest of the ilium and to within about two inches of the false ribs. The point of interest is that the limb had regained its temperature down to within two inches of the knee-joint. The hemorrhage was increasing, and I sent a note to my colleagues. While I waited, the subcutaneous hemorrhage seemed to ascend about half an inch.

The question was, What was to be done? The man was not in a condition for a hip-joint amputation, and the compound fracture was not one which under other circumstances would have demanded amputation. The collateral circulation had established itself to within two inches of the knee-joint. As there was nothing else to be done, it seemed to me that if the collateral circulation could establish itself under such adverse circumstances, it was possible that, if we secured the bleeding vessel and relieved the pressure upon the collateral circulation, it would doubtless maintain itself as far as it had gone, and might extend further and give an opportunity for secondary amputation.

I cut down, first, for the common femoral, and opened up a mass of blood and clot, and at once struck the artery, empty and contracted to two-thirds its size, but no wound was discovered. I next introduced my finger under Poupart's ligament into an enormous cavity. I found the iliac artery consisting for about half an inch of little but its stretched cellular coat, and I thought that I felt a rent in it. I passed a ligature, tying it above and below. It was found that one of the branches, I think the deep circumflex, had been torn off close to the iliac. I did not make the post-mortem, and am not quite positive as to the artery. The hemorrhage from this had ceased before I did the operation, for there was a clot in this branch and in the vessel. The vein appeared to be bleeding when I lifted it at the time. This I also tied. There was no more hemorrhage after the operation.

Where did the bleeding come from? The internal and middle coats of the external iliac were ruptured. The hemorrhage must have come from the arterial branch torn off, or the circulation must have been carried on through the injured external iliac, and come from the vein below. The fact that the collateral circulation set itself up so far is also interesting.

The further history of the case is that the man rallied and the foot seemed to me to get

warmer. The thigh retained its temperature, but the man gradually sank, and died about eighteen or nineteen hours later. The post-mortem showed that there had been no further hemorrhage. The external iliac had been tied three-fourths of an inch above Poupart's ligament. There was no fracture of the pelvis. Possibly if the vessel had been tied at first, the man might have rallied and the collateral circulation have been established in the limb below.

OPERATION FOR URINARY INCONTINENCE.

The President read the report of a case upon which he had operated for the relief of incontinence of urine:

A lady, who seven years ago had submitted to the operation of cystotomy for the relief of cystitis, consulted me some time since as to the propriety of closing the vesico-vaginal opening, as the constant flow of urine had become intolerable. The fistula was closed in the usual manner, by freshening its edges and uniting them together with silver sutures. It was found, however, that the urine still escaped involuntarily, and I supposed that the operation had failed at some point which had been overlooked. The parts were exposed, the bladder injected with milk and water, and found to be tight. The trouble arose from atrophic degeneration of the sphincter vesicæ, the result doubtless of long disease. To relieve this I proposed and executed the following operation. The mucous membrane was freshened at the neck of the bladder and for three-quarters of an inch forward, extending three-eighths of an inch on either side of the canal. After the denudation sutures were passed across the wound (not deeper than the submucous tissue), and the parts drawn together in a corrugated manner and secured by shot-clamps. The sutures were removed on the sixth day. No further trouble was experienced, and the patient remained perfectly dry.

A WANDERING STYLE.

Dr. Thomas G. Morton reported the following case: A lady came into my office a few days since, and stated that thirteen years since I had introduced, in her case, a gold style for a fistula of the tear-duct upon the left side. A week after the operation she stated that the head of the instrument, which was a small one, had disappeared. The fistule closed, and she had no further trouble until about two years ago, when she suffered considerably from facial neuralgia upon the left side. About this time she observed a pimple on the left side of the roof of the mouth, and soon afterwards this became an ulcer, and a hard, black substance like the end of a pencil projected and filled up the ulcerated part. This mass could be pushed up, but immediately reappeared when the pressure was removed.

An examination showed that the presenting hard body was the end of the style, which was readily removed with the aid of a dressing-forceps. The greater part of the style was thickly encrusted with calcareous deposit, which considerably increased its size. This, in addition to the head of the style, prevented its escape.

This is the only instance which has come under my notice where a style has worked its way through the roof of the mouth.

(To be continued.)

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, DECEMBER 10, 1885.

The President, J. C. WILSON, M.D., in the chair.

(Continued from page 258.)

DR. F. A. DERCUM presented the

BRAIN OF AN EPILEPTIC IMBECILE.

The dura was somewhat thickened, but not adherent. On puncturing it, five ounces of cerebro-spinal fluid escaped. The pia was adherent in a few places. The ependyma was reddened and injected, and the velum interpositum thickened. The convolutions were for the most part small, and the sulci shallow. The frontal convolutions were little more than outlined, and on the right the island of Reil was freely exposed. On each side the fissure of Rolando ran directly into the Sylvian. In the occipital lobes were the points of greatest interest. These lobes were remarkable for the smoothness of their surface. On the lateral surface only a shallow groove corresponded with the normal longitudinal occipital fissure. On the mesial surface the calcarine fissure was short and extended directly into the hippocampal, the posterior end bifurcated on the right, simple on the left. In the right hemisphere the parieto-occipital curved forward and ran for a short distance parallel with the fissure of the corpus callosum, then abruptly turned upward, terminating upon the lateral surface. A comparatively well-marked *pli de passage* was present, but made an obtuse angle of one hundred and twenty degrees with the calcarine. On the left the parieto-occipital made a right angle with the calcarine, and ran perpendicularly upward to end in a bifurcation on the lateral surface. On this side a large superior *pli de passage* was found. Microscopic examination of the paracentral lobule showed the cells in the upper part of the cortex, though numerous, rounded or irregular; in the lower part the cells were comparatively few; pyramidal cells were the exception, and only one or two of the usual large cells

were found. The walls of the vessels showed decided change.

The reporter remarked that the brain could only suggest atavism in a remote degree, being essentially an arrest of development, which was most marked in the frontal and occipital regions. Further, the condition of the pia and the lateral ventricles, with the excess of cerebro-spinal fluid, points to a brain essentially diseased.

Dr. FORMAD presented the

BRAIN OF AN IMBECILE.

As a young child the patient had been normal, the imbecility coming on after a sunstroke. The brain was markedly asymmetrical, the left cerebrum twice as large as the right, with an entire difference in the distribution of the convolutions. On the contrary, the right lobe of the cerebellum was twice the size of the left. The head was shaped to suit the brain.

Dr. DERCUM said that from the fact of the brain fitting so well into the skull, it would seem as though the condition might have been congenital. Still, in view of the traumatism and the age at which the symptoms commenced, he thought the condition rather one of atrophy. Not only were the primary convolutions perfect, but also the secondary: if it had been congenital, the secondary convolutions would most likely be absent, and the primary poorly formed.

Also, an

ANOMALOUS BRAIN,

from a boy, æt. 9 years. He had been healthy and of fully average ability. Death resulted from an accident. There is an entire absence of falx cerebri, the two hemispheres being connected by a bridge of brain-substance. There is nothing else abnormal.

Dr. FORMAD then continued his remarks on

THE CHARACTERISTIC LESIONS OF CHRONIC ALCOHOLISM,

and presented illustrative specimens.

Dr. J. P. STRITTMATER presented a

PRIMARY SARCOMA OF THE KIDNEY,

occurring in a child 5 years old. There was absence of a history of heredity. Enlargement of the abdomen was noticed soon after a fall, and progressed rapidly. The tumor — hard, rounded, and painless — extended from the crest of the ilium to the margin of the ribs on the left, with nodules extending to the median line. Towards the end the lower extremities became œdematous and the superficial abdominal veins enlarged. She died four months after the first symptoms. Post mortem, the left kidney was found enlarged to the size of a fœtal head, with a complete destruction of any normal structure. There were secondary deposits in the peritoneum, omentum, liver, spleen, and right lung.

Dr. FORMAD said he had examined the growth and found it to be a congenital rhabdomyoma, which had undergone sarcomatous change. Primary renal sarcomata rarely give metastasis, and he accounted for the numerous secondary growths in this case by the fact that the sarcomatous change was secondary to the rhabdo-myoma.

Dr. T. S. K. MORTON presented specimens from a case of

PNEUMONIA WITH MENINGITIS.

The patient, when first seen, five days after the initial symptoms, was profoundly comatose and rigid, with finely-contracted pupils and the physical signs of pneumonia. She died in a few hours, with no change in the symptoms. The dura was in spots slightly adherent. Extending the whole length of the longitudinal sinus was a firm white clot. A small vein, occluded by the clot, had ruptured and poured out about a drachm of blood. There was extensive suppurative lepto-meningitis, with considerable effusion in the ventricles. The upper lobe of the right lung was in a state of advanced red hepatization.

Dr. J. H. MUSSER said the extreme interest of this case arises from the association of apex pneumonia with meningitis, without any lesion in the body as ulcerative endocarditis or any septic process to account for their concurrence. As is well known, in apex pneumonia cerebral symptoms are very prominent, and, being attributed to functional disturbance of the brain, at the present day there is no attention paid to the active treatment of them. This case teaches the valuable lesson that we must learn to treat these symptoms more actively in many cases or we may expect frequently disastrous results.

Dr. TYSON said that, notwithstanding the absence in the history of any traumatism, he could not but think there might have been a blow on the head which was responsible for the pneumonia.

The PRESIDENT remarked that the absence of any history of traumatism in the case by which the meningitis might have been caused brought into prominence the lesions of chronic alcoholism, a condition in itself strongly predisposing to meningitis. The cerebral symptoms appear to have been not only more intense, but also different in kind from those met with in pneumonia, and particularly apex pneumonia. Though perhaps not more intense than is sometimes seen in the apex pneumonia of children, they were certainly different in character. The association of the two diseases pneumonia and meningitis he thought accidental rather than causal.

Dr. C. M. WILSON presented a

MENINGOCELE

taken from a patient dying sixteen days after

birth. The brothers and sisters were healthy, but the youngest had in the temporal region a nævus. The child died in convulsions. The tumor, which grew from the posterior fontanel, was as large as an English walnut, was filled with cheesy matter, and its cavity could be reached from the interior of the cranium.

The Committee on Morbid Growths reported: (1) Dr. Dunn's specimen, removed from the lumbar region of a cow, shows a combination of myxoma with lipoma; (2) Dr. Roberts's tumor, removed from the theca of the extensor tendon of the middle finger, shows the structure of a pure fibroma.

CARD SPECIMENS.

Dr. W. W. Edwards: Head and Neck of a Tænia Solium.

Dr. Morton: Bony Tumor projecting from Right Side of Falx Cerebri.

Dr. J. M. Keating: Congenital Cystic Liver.

Dr. R. G. Curtin: Tricuspid Insufficiency.

Dr. J. S. Neff: Chronic Endo- and Pericarditis. Heart weighing fifty-six ounces.

Dr. Tyson: Acute Pericarditis.

Dr. Formad: Acute Pericarditis; Heart with Three Ventricles; Rhabdo-myoma of Kidney: Two Cases of Spina Bifida; Congenital Diaphragmatic Hernia; Congenital Occlusion of Rectum.

W. E. HUGHES, M.D.,
Recorder.

REVIEWS AND BOOK NOTICES.

ACNE: ITS ETIOLOGY, PATHOLOGY, AND TREATMENT. A Practical Treatise based on the Study of One Thousand Five Hundred Cases of Sebaceous Disease. By L. DUNCAN BULKLEY, A.M., M.D., etc. New York and London, G. P. Putnam's Sons. 1885. Octavo, pp. 280.

Dr. Bulkley's latest volume is one of the best, if not the very best, of the works that have proceeded from his fertile pen. It is a monograph of high value, and gives additional lustre to the fame of American dermatology. The fault which we found with his monograph on eczema—that of a redundancy of style and matter so great as markedly to impair the interest of the book—has, fortunately, in great measure been avoided in the book before us. The style, without being at all concise, is not wordy, and there is little in the work that can safely be skipped.

The book opens with a discussion of the anatomy and physiology of the sebaceous glands. This portion is illustrated by a number of original cuts. Then follows a chapter on classification, nomenclature, definitions, etc. At this point is interpolated a chapter on the frequency of sebaceous diseases, with the statistics of fifteen hundred cases. This part, we think, might have been condensed with advantage. After another chapter on the etiology of sebaceous diseases, Dr. Bulkley goes on to discuss the various affections which he includes under the designation of acne. These embrace diseases like seborrhœa, comedo, milium, and acne molluscum, which have not hitherto in this country been classified as acne. Dr. Bulkley is, we are inclined to think, right in classifying these non-inflammatory affections of the sebaceous glands with the inflammatory ones, as they certainly come under the same general category.

That portion of Dr. Bulkley's book which discusses the etiology, treatment, etc., of the different affections is, of course, practical and interesting. Departing from the plan followed in his monograph on eczema, Dr. Bulkley gives occasionally the story of some individual cases, which add liveliness to his pages and illustrate like pictures the general principles of management laid down in the text.

Regarding treatment, we regret that Dr. Bulkley has found it convenient to place all his formulæ at the end of his book, as it is awkward for any one reading it to refer back and forth so frequently as is necessary in many cases. Our experience with this plan of putting all the formulæ together has been that it is annoying to the student, while extremely attractive to the hungry fisher of prescriptions, who flies to the formulary convinced that, if he can only copy a sufficient number of "recipes" into his note-book, he shall be possessed of all the author's wisdom.

The directions as to the general management of the various affections, and especially the principles of treatment laid down, are in the highest degree important and interesting, and, did space permit, it would be interesting to comment upon this portion of Dr. Bulkley's book.

We cannot close this notice, however, without alluding to one point in the etiology of acne as discussed by Dr. Bulkley. This is the relation between sexual derangements in the male and diseases of the sebaceous glands. Dr. Bulkley says that, "although the actual marriage state does not appear to have very much effect upon the occurrence of acne, it is undoubtedly true that unnatural sexual life may, and often does, have much influence upon its production." A great deal of pernicious nonsense has been written upon this subject, and much humiliation and mortification have been caused by blunt assertions of sexual immorality made by physicians to young men suffering from acne. While boys and young men of delicate health and sedentary and seclusive habits are more apt to indulge in vicious ideas and practices than robust youth given to out-door and gregarious pursuits, the acne which we meet with in the former is due to ill health directly, and not to

unnatural sexual indulgence. Such, at least, is the invariable experience of the reviewer from a long familiarity with and study of cases of acne occurring in youth.

A Reference Hand-Book of the Medical Sciences: Embracing the Entire Range of Scientific and Practical Medicine and Allied Sciences. By various Writers. Illustrated by Chromo-Lithographs and fine Wood-Engravings. Edited by Albert H. Buck, M.D., New York City. Volume I. New York, William Wood & Co., 1885. Quarto, half-morocco, pp. 808.

The scope of this magnificent work is encyclopædic,—embodying, as it does, contributions from various authorities, treating in a compendious manner the principal subjects upon which medical men are likely to desire information. Consisting, when complete, of eight volumes of about eight hundred pages each, it will constitute in itself a valuable reference library. The editor has wisely pursued the course of selecting the topics to be discussed, giving the most space to matters of a practical nature, such as diagnosis and treatment, but at the same time not neglecting to make ample provision for such departments as medical botany, climatology, embryology, physiological and pathological chemistry, applied anatomy, medical jurisprudence, military and naval surgery. The first volume is handsomely printed, in double column, with clear type, and is freely illustrated with excellent cuts and some full-page chromo-lithographs. The subjects extend from Aachen to Cataract; the principal articles are signed by their writers, and are almost without exception of marked value as epitomes of the present state of knowledge on the various topics treated. We had intended to notice some articles which especially attracted attention, but, as mention might be invidious where the work is so uniformly good, we will simply confine our congratulations to the editor, and predict for this work a very favorable reception by the profession.

Leonard's Physician's Pocket Day-Book. Bound in Red Morocco, with Flap, Pocket, and Pencil-Loop. Price, postpaid, one dollar. Published annually by the *Illustrated Medical Journal* Company, Detroit, Michigan.

This popular day-book is now in its ninth year of publication. It is good for thirteen months from the first of any month on which it may be begun, and accommodates daily charges for fifty patients, besides having cash department and complete obstetric records. There are also columns for the diagnosis of the case or for brief record of the treatment adopted following each name-space. Name of patient needs to be written but three times in a month.

Physician's Visiting-List, 1886. Thirty-Fifth Year of its Publication. Containing Calendar, List of Poisons and Antidotes, Dose-Tables rewritten in Accordance with the Sixth Revision of the United States Pharmacopœia, Marshall Hall's Ready Method in Asphyxia, Lists of New Remedies, Silvester's Method for Producing Artificial Respiration (with Illustrations), Diagram for Diagnosing Diseases of the Heart, Lungs, etc. Lindsay & Blakiston, Philadelphia.

This pocket day-book is bound in morocco, and fastens with a flap. Besides the visiting-list, it contains some tables for ready reference, giving important hints for emergencies. It is a favorite day-book with busy physicians.

The American Journal of the Medical Sciences, the oldest American medical journal, appears with a new arrangement in its January issue, which contains a number of contributions from English as well as from American sources. Its editor has taken this step and secured a corps of contributors in Great Britain with the avowed object of making it "the international representative of the medical thought and work of the English-speaking races." As it has always been devoted to the best interests of the medical profession, all are interested in its permanence and success, and its new departure will be welcomed, as it widens its field of usefulness.

Lippincott's Monthly Magazine will appear hereafter on the first day of each month. Under its new editor a number of changes have been made which decidedly increase its attractiveness: it has a new cover of very neat design; the old double-column page has been replaced by a leaded full-width page; and illustrations have been omitted. It is handsomely printed, and very inviting in appearance and in contents. The subscription-price has been reduced to two dollars, and the *Times* and *Magazine* will both be sent for one year for three dollars and twenty-five cents.

Mimik und Physiognomik.—An enlarged and complete edition of this work, by Dr. Theo. Piderit, has just been issued by the Meyer Publishing-House in Detmold. This work, when it first appeared, attracted marked attention on account of originality in the treatment of the subject; and in the second and greatly-improved form it will be welcomed by those especially interested in its scientific consideration.

The Medical Times and Gazette discontinued publication at the close of the year. It was one of the old London weeklies, and its discontinuance is a decided loss to medical journalism.

THE AMERICAN PRACTITIONER AND NEWS.—The *Louisville Medical News* of December 26 contains a notice of consolidation, on the first of the year, of the *News* with the *American Practitioner*, to be issued as a bi-weekly, with the above title, under the editorial management of Drs. D. W. Yandell and H. A. Cottell.

THE MEDICAL PRESS OF WESTERN NEW YORK, published at Buffalo, is a welcome addition to journalism. It is well printed and well conducted, and will doubtless receive hearty support from the profession.

NEW BOOKS.

HAND-BOOK OF THE DISEASES OF THE NERVOUS SYSTEM. By JAMES ROSS, M.D., LL.D. With One Hundred and Eighty-four Illustrations. Lea Brothers & Co., Philadelphia, 1885. 8vo, sheep. Pp. 723.

TEXT-BOOK OF OPHTHALMOSCOPY. By EDWARD G. LORING, M.D. Part I. Illustrated. D. Appleton & Co., New York, 1886. 8vo. Pp. 274.

A TREATISE ON THE DISEASES OF INFANCY AND CHILDHOOD. By J. LEWIS SMITH, M.D. Sixth Edition, thoroughly Revised, with Forty Illustrations. Lea Brothers & Co., Philadelphia, 1886. 8vo, sheep. Pp. 867.

TRANSACTIONS OF THE ACADEMY OF MEDICINE IN IRELAND. Vol. III. Dublin, 1885.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. III. 1885.

A MANUAL OF MICROSCOPICAL TECHNOLOGY. By DR. CARL FRIEDLAENDER. Translated, with permission, by STEPHEN YATES HOWELL, M.D. G. P. Putnam's Sons, New York and London. 12mo. Pp. 249.

MISCELLANY.

MIZU AME, OR JAPANESE MALTINE.—Dr. J. C. Berry, of Okayama, gives the following interesting account of the process of manufacture of *Mizu Ame* in Central Japan:

1st, Malt (*moyashi*). Made by putting barley into a pail with a perforated bottom, and then moistening with water for two weeks, by which time (varying with the weather) the barley germinates. Spread and dry, rub off the sprouts, winnow and grind, when it is ready for use.

2d, Of *mochi-gome* (the very glutinous rice from which the *mochi* is made) one *to*,* cook the rice by steaming in a wooden box until moderately soft. Remove to a pail, and add: malt, four hundred and fifty *momme*,† water five *sho*.* Then with the hands thoroughly mix the whole, squeezing and crushing the rice until it assumes a hard, jelly-like consistence; then allow it to remain for twelve hours, during which time stir three times. (If the weather is very cold, it is covered with straw mats; if very warm, it is kept in a cool place.) Remove, and place in hempen bags, put into a strong box, and press out the liquid with firm pressure. Lastly, evaporate to proper consistence over a slow fire.

Mizu ame was never used in Southwestern Japan other than as an article of diet for babies, weakly children, and old people, until recently, and at present its use is largely confined to those who have been brought in contact with or instructed by foreign physicians. I have used it considerably during the last five years, more especially in cases where food-medicines are required; and, after being properly diluted, frequently prescribe it with dialyzed iron and with cod-liver oil. I use it more or less on my table as an article of diet, instead of syrup or honey, especially with one of my children who has a weak stomach. I imagine that its one single advantage over malt or maltine is its more easy digestibility. —*Supplement to Transactions of Sei-I-Kwai.*‡

COLLEGE OF PHYSICIANS OF PHILADELPHIA.—At the January meeting, held on the 6th instant, Colonel George E. Waring, Jr., of Newport, R.I., delivered an address on "The Disposal of Sewage and the Protection of Streams used as Sources of Water-Supply."

After the address a business meeting was held, at which reports of committees were received and an election for officers and committees held. The following were elected for the ensuing year:

President, Dr. S. Weir Mitchell; Vice-President, Dr. John H. Packard; Secretary, Dr. Isaac Norris; Treasurer, Dr. Charles Stewart Wurts; Honorary Librarian, Dr. James H. Hutchinson; Recorder, Dr. J. Ewing Mears; Censors, Drs. Lewis Rodman, William Goodell, Alfred Stillé, Samuel Lewis; Councillors (to serve until January, 1889), Drs. Richard A. Cleemann, William Thomson; Committee on Publication, Drs. James H. Hutchinson, Robert P. Harris, Arthur V. Meigs, J. Ewing Mears; Committee on Library, Drs. I. Minis Hays, Samuel W. Gross, Morris Longstreth, George C. Harlan, William Osler; Committee on Mütter Museum, Drs. William Hunt, John H. Brinton, Morris Longstreth; Committee on Hall, Drs. Horace Y. Evans, Thomas Hewson Bache, J. Ewing Mears, Morris J. Lewis, William Barton Hopkins; Committee on Lectures, Drs. Joseph Leidy, William Goodell, William F. Norris, John H. Packard, Samuel W. Gross; Committee on Directory for Nurses, Drs. William W. Keen, Wharton Sinkler, James C. Wilson.

PHILADELPHIA COUNTY MEDICAL SOCIETY.—At the annual meeting for the election of officers, held January 6, the following were elected for the ensuing year:

President, Dr. R. J. Levis; Vice-Presidents, Drs. William R. Cruice, Charles Wittig; Re-

* 1 *to* = 10 *sho* = 1097 cu. in.
† 120 *momme* = 1 lb. avoirdupois.

‡ Mizu ame has been imported and is on sale by Mr. G. I. McKelway, of this city.

cording Secretary, Dr. S. Solis-Cohen; Assistant Secretary, Dr. Benjamin F. Nicholls; Corresponding Secretary, Dr. M. S. French; Reporting Secretary, Dr. William H. Morrison; Treasurer, Dr. L. K. Baldwin; Censor, Dr. F. P. Henry; Librarian, Dr. C. M. Seltzer.

The following was, on motion of Dr. D. Hayes Agnew, adopted by the Society:

"*Resolved*, That at its annual election of delegates to the American Medical Association and to the State Medical Society the Philadelphia County Medical Society desires to express its regret at the action of the American Medical Association at New Orleans, in view of the injurious results which followed to professional harmony and to the prospects of the International Congress.

"*Resolved*, That the delegates from this Society be instructed to endeavor to secure such modification of that action as may best conduce to the re-establishment of professional harmony and to the success of the Congress."

PHILADELPHIA HOSPITAL.—At the December meeting of the Guardians Dr. Philip Leidy, formerly Port Physician, was elected Chief of the Insane Department of the Philadelphia Hospital in place of Dr. D. D. Richardson, and Dr. Andrew Nebinger was elected Consultant in place of Dr. H. C. Wood. Drs. S. Weir Mitchell and C. K. Mills were also elected Consulting Physicians to the Insane Department. The attending staff of the Department for the Sick was re-elected and enlarged,—Drs. William Osler and John H. Musser being added to the Medical, Drs. Alexander W. Ransley and L. W. Steinbach to the Surgical, and Drs. Elliott Richardson and E. E. Montgomery to the Obstetrical.

COLDEN'S LIQUID BEEF TONIC.—This excellent preparation has become deservedly popular with the medical profession in the treatment of diseases where an agreeable article of diet and tonics are required. It is recommended in typhoid and malarial fevers, consumption, loss of appetite and debility induced by any cause, and it is tolerated when other forms of animal food are rejected.—*Maryland Medical Journal*, Baltimore, Md.

NEW YORK ACADEMY OF MEDICINE.—A Laryngological Section was formed December 23, when an interesting paper was read by Dr. R. P. Lincoln, entitled "The Surgical Uses of Electricity in the Upper Air-Passages," which led to a general discussion. Dr. Lincoln was elected chairman of the Section, and Dr. D. Bryson Delavan Secretary.

THE annual address before the Academy of Surgery of Philadelphia was delivered by Dr. R. J. Levis on last Monday evening, January 4, at the hall of the College of Physicians, the subject being "Impediments to the Progress of American Surgery."

NOTES AND QUERIES.

OBITUARY.

JOSHUA B. LIPPINCOTT, the founder of the publishing-house and the president of the J. B. Lippincott Company, died on the 5th instant at his home in this city, aged seventy-four years. For a long time he had been a sufferer with nephritis, and two years ago he had an attack of pneumonia, followed by a disorder of the heart, which seriously undermined his health. During last year it became evident that health could not be regained, and death appeared imminent. In view of this change, he made arrangements to have the great business which he had built up continued after his death by converting it, last February, into a stock company.

Mr. Lippincott was known to the profession as the publisher of many of the standard medical works, and of *Lippincott's Magazine* and the *Philadelphia Medical Times*. He was one of the Trustees of the University of Pennsylvania, and took a warm interest in all matters connected with medical education.

PARTURITION IN THE NEGRO.

TO THE EDITOR OF THE PHILA. MEDICAL TIMES:

Having been connected with the medical profession for several years, there have arisen during that time many questions with seemingly no answers to them,—at least none satisfactory to me,—and among them is the ease with which the negro woman (the genuine black woman) gives birth to her children. And why is she so much more exempt from the diseases incidental to the lying-in period than the white woman? for a few days, in a general way, is all that she observes. During the whole of my professional life I have but once seen the necessity for using the obstetrical forceps. I have seen not one unnatural presentation, and but two cases of eclampsia, one before and the other after birth. Neither have I seen a case of puerperal fever, milk-leg, prolapse nor retroversion of the uterus. I have never known one to die in labor, or from any of its sequels, in this community. But as soon as we leave the genuine black race and approach the Anglo-Saxon, troubles and tribulation among the female sex stand thick on every hand. These black women are more exposed to the climate, and are less well fed and clothed, living in huts or small houses,—many without windows or plastering,—with nothing but the naked weather-boarding between them and the heavens, and yet they seem to have no more trouble than the animal creation. They sicken and die with the diseases of the climate, like the white race, but in this Providence has in his wisdom seen proper to protect them. But outside of this there must be some law that governs them which the Anglo-Saxon race would do well to study and to bring into practice. It occurs to me, if it works well with negroes, why not with the white race in the same cases? I think my experience will compare favorably with that of other physicians.

Yours, J. A. H.

MILTON, DELAWARE, December 5, 1885.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM DECEMBER 20, 1885, TO JANUARY 2, 1886.

FRYER, B. E., MAJOR AND SURGEON.—Sick-leave extended six months on surgeon's certificate of disability. S. O. 292, A. G. O., December 21, 1885.

VICKERY, R. S., MAJOR AND SURGEON.—Relieved from duty in Department of Columbia, to repair to Washington, D.C., and report in person to Surgeon-General for duty in connection with Army and Navy Hospital, Hot Springs, Arkansas. S. O. 293, A. G. O., December 22, 1885.

REED, W., CAPTAIN AND ASSISTANT-SURGEON.—Leave extended one month. S. O. 293, A. G. O., December 22, 1885.

MADDOX, THOMAS J. C., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Killed December 19, 1885, in affair with Apache Indians near the White House, New Mexico.

IVES, F. J., ASSISTANT-SURGEON.—Ordered to report to commanding officer, District of New Mexico, for duty in the field. S. O. 127, Department of the Platte, December 23, 1885.

PHILADELPHIA, JANUARY 23, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE PRESENT SCOPE AND AIM OF ELECTRICITY IN MEDICINE.

BY JAMES HENDRIE LLOYD, M.D.,

Instructor in Electro-Therapeutics in the University of Pennsylvania.

(Delivered to the Fourth Year Class.)

GENTLEMEN,—It is cause for congratulation that a therapeutic agent which has been so often misapplied by empirics and so generally abused by charlatans has been of late years so thoroughly submitted to scientific methods that it has attained a name for approximate certainty which is clearly excelled by very few drugs. That these severe tests have narrowed its realm and curtailed its prerogatives in many ways may be disappointing to the "electropath," but to the true scientist it is perhaps only an additional guarantee that what is known is genuine and what is discarded is false. The scope of the science is, in truth, not very ample. It includes, as its most striking feature perhaps, the results obtained in diseases of that neuro-muscular apparatus which is made up of the trophic cells in the anterior horns of the cord, the peripheral nerve, and the muscles of distribution. This apparatus forms an important half of that reflex arc which is the only nerve-organism of the lower forms of animal life. This fact would seem to suggest the propriety of testing these lower forms of life for identical results with those obtained in man, which would require a nicety of experiment to which our therapeutic instruments are not adapted. This subject suggests another query. Since the irritability of the cortex cerebri has been proved, and certain motor points seemingly established, would it not be well to have the qualitative and quantitative reactions of these motor points more thoroughly investigated, and especially with a view to any possible reaction of degeneration? The writer does not recall that in the experiments of Ferrier and others such investigations have been made.

The contributions of electro-therapeutics to the diagnosis and treatment of these trophic diseases alone merit for the science the respect and confidence of the profession, and remove from it the opprobrium of being the true handmaid of quackery. That we have an agent which will tell us, often before changes are visible, that the trophic centres are involved is a fact of obvious importance, as is also the fact that a hysterical paralysis can often by the same agent be ferreted out and distinguished from the far more serious anterior poliomyelitis. In this connection, however, it is well to emphasize an important point,—viz., that the abnormal reactions are, as their name signifies, the reactions of *degeneration*, and not merely of *paralysis*. Hence, in mild forms of peripheral palsy due to pressure or traumatism, it is not common to find the reactions of degeneration, because degeneration does not occur. I have very generally failed to find all the abnormal reactions in light forms of wrist-drop due to pressure of the head on the musculo-spiral nerve during drunken sleep. The changes observed in these cases have usually been a slightly diminished faradic contractility, and perhaps a somewhat prolonged contraction of the muscle to galvanism, results which are to be expected in healthy muscular tissue when cut off from nerve-influence. These conclusions are confirmed by several cases observed during the last fall.

The following case is an illustration of more serious peripheral paralysis:

M. G., middle-aged man, suffered from a pistol-wound which had been self-inflicted, by accident, near the elbow-joint. The ulnar nerve lay almost between the wounds of entrance and exit, and had been no doubt grazed by the ball. There was no paralysis at first, but very severe pain in the course and distribution of the nerve. Treatment by anodynes and local revulsives was ordered, but the patient soon became careless and absented himself from the hospital for a period of six weeks. When he returned, the limb presented the characteristic appearance of profound change in the ulnar group of muscles. The flexor of the wrist and deep flexor of the fingers were much wasted, the interosseous spaces were hollowed out because of the loss of the little interosseous muscles, and the inner margin of the thenar eminence was lessened by the wasting of the adductor of the thumb. The reactions of degeneration were marked. Faradic contractility much diminished, in some muscles perhaps abolished. To galvanism there was diminished response, long, slow contractions, and the

anode at closure produced more response than the cathode. Prognosis in this case was guarded, but in the main hopeful. The man has again absented himself. The treatment would have been galvanism, because that current alone excited the muscle to contract; but as soon as faradic contractility returned, this current would have been preferred as more stimulating to the muscles and more convenient to apply.

I believe faradism is more stimulating to muscles because of the mere mechanical effect of numerous rapidly-repeated irritations. It requires, however, a certain degree of activity in the nerve, as muscular tissue alone will not respond to it. Therefore in such a case as the foregoing it would be useless to employ it until repair had gone far enough to allow the injured nerve to regain influence over the muscle, as would be shown by the muscle responding to the induced current.

The following case illustrates the practical value of electro-diagnosis:

T. B., a negro, had paralysis of the facial nerve, with slight inequality of the pupils (but no ptosis or strabismus), also much vertigo and some deafness. There was grave suspicion of a syphilitic taint, and it was desirable to eliminate the possibility at least of cortical or meningo-cortical lesion. The reactions of degeneration were found in the facial muscles, which proves a peripheral lesion. The inequality of the pupils was found to have depended upon some eye-drops which a neighbor had given the patient, and which no doubt contained atropine; and the diagnosis was of syphilitic disease of the temporal bone, causing pressure on the facial nerve. In this case the electro-diagnosis, if not essential, was at least confirmatory.

In simple rheumatoid neuritis of the facial it has seldom been my misfortune to see a case advance to *total* abolition of faradic contractility. The Nervous Clinic at the University has presented three or four cases of the disease during the last fall, in all of which we had diminished faradic contractility, with quantitative increase to galvanism followed by decrease, and slight abnormal change in anodal and cathodal electrotonus. In these so-called *partial* reactions of degeneration I think it is sufficient for us to accept the facts without trying to explain them by elaborate schematic drawings, which are at best but theoretical. There may be a difference between myo-trophic and neuro-trophic centres in the spinal cord (?), but the fact did not appear until made necessary by the obscure phenomena of partial degeneration reaction.

In orthopædics it seems probable that much more use could be made of electricity for diagnostic purposes than is the custom, in our midst at least. The club-feet of children are doubtless caused by attacks of anterior poliomyelitis in limited areas, causing paralysis and degeneration of muscles, either separate or in groups. To understand the mechanism of these deformities, it is quite essential to know what individual muscles are involved, and not only what the exact action of these muscles is, but also the effect of their paralysis upon other muscles which have been to them diverse forces of resistance. To detect these muscles by electro-diagnosis would seem to be theoretically quite possible; but in practice there are obstacles which are not always easily overcome. The diffusion of the current to adjacent muscles is often a source of confusion: this is best overcome by using an olive-pointed electrode and by knowing exactly the motor points. Another source of error possibly is the fact that the disease is not far advanced, and we may therefore have only the partial reactions of degeneration above referred to. A difficulty is also found in the fact that some of the muscles are very deep seated. This is true especially of such muscles as the extensor proprius pollicis and the long flexors of the toes. I have found that a response is best secured in such muscles by applying the electrode along the tendon as close up to the muscular tissue as possible, just where it emerges from beneath the superimposed tissues.

There is a condition of muscle called subacute rheumatism, which is probably not rheumatic, but is more properly a myalgia, or, better, a subacute myositis. We have doubtless in these muscles nutritive changes which amount to a limited hyperplasia and which bind the muscle down. Such troubles are more often caused by over-use, strain, or direct injury than aught else, and the remedy for them in the chronic stages is, *par excellence*, faradism. It can be used by ordinary sponge-electrodes; and a tetanization of the muscle by the rapid interruptor is time-saving and perfectly harmless. The success of this treatment probably de-

pends upon the "breaking-up" of this hyperplastic condition. I have seen it act well in lumbago, while the patient amused himself with salicylic acid. It is especially serviceable about the shoulder-joint, as the following case testifies:

B., a professional base-ball player at "short stop," had severely strained his supra- and infra-spinatus and biceps muscles by a long throw. He had passed the acute stage, but the joint remained stiff and painful. The application of the faradic current as just mentioned gave relief from the very beginning of treatment.

It is customary to say that the galvanic current, especially the positive pole, is a remedy for neuralgia, and Billroth's wonderful case is made to do duty again as an example. I can only say that its use is often disappointing and never, in my experience, attended by remarkable results. It is sometimes palliative, however, and therefore worthy of trial.

The electrolytic and so-called catalytic action of the galvanic current is constantly attracting more attention. The good effects of this treatment are recorded in stricture of the urethra, in fibroid tumors of the womb, in the nutritive and inflammatory diseases of the female pelvis, and in aneurism. These diseases do not come within the range of neurology, but a few comments are not inappropriate.

Dr. Paul Mundé, in a recent paper, has recorded his observations with electricity in gynæcological practice, and it is interesting to note that his practical experience is in accord with theoretical data. Faradism is indicated most probably by reason of its stimulating effects upon muscular tissue, and hence has been found useful in cases especially of deficient development of the uterus, in subinvolution and displacements; while galvanism has benefited the hyperplasia following the various inflammations of the female viscera. In obstetrics it would be worth while perhaps to try faradism more frequently in premature and retarded labors and in some cases of post-partum hemorrhage. In the treatment of aneurism the criticism of De Watteville is all-important. He claims that failures result from not using a sufficient intensity of current, which ought to reach from forty to fifty milliampères in order to obtain the electro-chemical effects. These results could only be obtained, of course, by the use of a proper electro-motive force in reference to the resistance to be overcome, and by taking accurate measurements with a galvanometer.

The measurement of current-strength in the medical use of electricity is now a recognized necessity. We must no longer use our agent without measuring the dose. No results can be accepted as exact, especially in diagnosis, without a test of current-intensity. The difficulty was that our manufacturers were not able to give us a reliable "dead-beat" instrument at a suitable price. Several galvanometers are now offered; one of the surest of which no doubt is the Edelman, the price of which, however, is high. Mr. Flemming, of this city, makes one, after the pattern of Hirschmann, which he has had carefully tested at the Franklin Institute, and which he has found correct. It is now in use at the University Hospital, where it gives satisfaction. It is easily read, because of the vertical position of the needle, and is not an expensive instrument. It is not perfectly "dead-beat," and requires shunting by a system of pegs, which are its only disadvantages. A simple reference to Ohm's law demonstrates the use of this instrument. With a number of cells representing about 20 volts and a human arm, which has probably 2500 ohms resistance, we obtain, by dividing the force by the resistance, $\frac{20}{2500}$, which equals $\frac{1}{125}$ of an ampère, which is 8 milliampères—as shown on the dial of the instrument.

ORIGINAL COMMUNICATIONS.

REMOVAL OF THE UTERINE APPENDAGES.

Read before the Philadelphia County Medical Society, October 22, 1885,

BY WILLIAM H. PARISH, M.D.,
Professor of Anatomy at the Woman's Medical College of Philadelphia.

THE different conditions for which removal of the ovaries alone, or of ovaries and tubes, has been resorted to—most of which I shall advocate as warranting the operation, but in reference to some of which I shall raise a word of caution, if not of protest—may be classed under the following heads:

1. Diseases of the uterus.

2. Diseases of the tubes.
3. Diseases of the ovaries.
4. Disturbances of the general system, but especially of the nervous system.

Let us consider the last division first. It has long been an established fact that manifestations of abnormal nervous phenomena almost invariably are most marked at the menstrual epoch. Between such manifestations and the female sexual apparatus there is a close bond of sympathy. At the time of ovulation, the despondent are often most depressed, the irritable are most excited, and the hysterical, the epileptic, the maniacal, and the hypochondriacal insane each, usually, present in their most typical forms the evidences of their diseases. With them the congestion and hyperæsthesia pertaining to ovulation seem still further to unhinge the disordered nervous system. Undoubtedly, the process of ovulation does modify and usually aggravates functional or organic perturbation of the nervous system, and there can be no question but that hysteria, hystero-epilepsy, true epilepsy, or insanity may be determined or may be perpetuated by disturbed ovulation.

The removal of the ovaries, however, cannot be considered justifiable merely because abnormal nervous phenomena are most marked at the time of ovulation, even though the nervous disease is of as severe a type as epilepsy or insanity. It should be shown—at least there should be the strongest reason for believing—that the epilepsy or insanity is directly dependent upon the ovulation. The mere aggravation of the symptoms at the menstrual epoch is far from being a sufficient proof that ovulation has determined or is perpetuating the nervous disease. When ovulation merely aggravates the disease, the abnormal nervous phenomena will appear at the intermenstrual periods, and the exciting causes will be numerous and varied: anger, excitement, fatigue, indigestion,—one or more,—will awaken the attacks. If, however, epilepsy or insanity appear only at the menstrual periods, and not between those epochs, and this has been observed for months, and the periodical return has resisted other well-directed remedies, and there exist, as is usually the case, other evidences of disturbed ovulation, then there is, to my mind, a sufficient warrant for the belief that ovulation has originated the epilepsy or the insanity, and is perpetuating it. In such cases the disease will become more and more firmly established as time passes, and eventually will not be limited to the ovulation period.

Such cases are doubtless very rare; but they do exist. And in such, after having failed to secure relief in other ways, the removal of the ovaries is an obligation resting heavily upon the medical attendant. In such cases experience has shown that to stop ovulation is to stop the epilepsy or the recurrent insanity, for there are on record a few cases in which the disease has been apparently permanently cured by the removal of the ovaries, and the accomplishment of—to use Battey's words—"the great nervous revolution which ordinarily accompanies the climacteric."

I will go a little further in reference to these two most grave diseases, epilepsy and insanity, and claim that there are a few cases in which the uterine appendages should be removed, even though intermenstrual epilepsy or insanity exist. I refer to cases in which the type changes at the period of ovulation so as to present at that time—and only at that time—mania or homicidal tendencies. When an epileptic or an insane woman is harmless during the intermenstrual period and becomes a maniac or prospective homicide during the period of ovulation, the indication, amounting to an obligation, is to stop ovulation by the removal of the ovaries and tubes, other remedies having been duly tried. By so doing, one may prevent the recurrence of mania and of the homicidal insanity. In most instances, when the symptoms have shown the dependence of epilepsy or of insanity "upon ovaries viciously performing their functions," the ovaries at the time of opening the abdomen have presented evidences of organic abnormality, though such abnormal condition may not have been ascertainable by any examination prior to the performance of laparotomy.

Hystero-epilepsy is undoubtedly dependent largely upon an irritation of the nervous system reflected from the ovaries, especially at the menstrual nisus. But hystero-epilepsy is of much less serious nature than epilepsy or insanity, and is more amenable to treatment by means which in themselves bring no risk to the patient. Experience has shown that this

disease usually disappears in time, under well-directed treatment of mind and body. The hystero-epileptic, generally, in a few years becomes a useful woman, and possibly a mother. It is true she often transmits her nervous temperament, her nervous enfeeblement, to her offspring; but this fact does not justify the surgeon in rendering child-bearing impossible. While in some minds the removal of the ovaries may be justifiable in the confirmed epileptic or in the confirmed insane, in order to prevent offspring, yet there can be no question as to the indefensibility, if not criminality, of performing this operation with such a view in a hystero-epileptic.

Hystero-epilepsy, however, may be but one of several symptoms resulting from established lesions of the uterine appendages. In such a case Battey's operation is possibly demanded, because of otherwise incurable pelvic disease. The existence of hystero-epilepsy, then, does not of itself warrant the removal of the uterine appendages; and, on the contrary, its existence does not contraindicate the operation when other and sufficient indications exist for its performance.

In reference to the still less serious disease, hysteria, the unanimous opinion of prominent gynæcological surgeons, as shown in their writings, is that the disease, absolutely, does not justify Battey's operation; nor did Battey intend that his operation should be performed because of hysteria alone. Battey states very positively, also, that the operation should not be resorted to in the treatment of uncomplicated nymphomania, for the removal of the ovaries would not prove curative, not even palliative, of that condition, just as their removal does not lessen the normal sexual desire.

There are other systemic reflexes of ovarian origin which occasionally disturb the health to such an extent as to warrant the removal of tubes and ovaries. When invalidism has been established for years by reason of a nervous exhaustion dependent upon ovarian reflexes; when anorexia and persistent vomiting; when functional cardiac disturbance and enfeebled blood-circulation; when wakefulness and reflected neuralgias,—have established an invalidism that has resisted for years the most skilfully directed remedies within the patient's reach; when, as a result, the establishment of some fatal disease is pending,—then the removal of the ovaries and tubes will probably supplant invalidism and impending fatal disease with health and probably long life. Such symptoms justified, in Battey's mind, the performance of his operation, and his experience, with that of other surgeons, has proved the correctness of his *a priori* reasoning.

Careful examination, microscopically as well as macroscopically, has shown that, where ovaries have been removed by reason of serious failure of health dependent upon ovarian disturbance, the ovaries have not been normal, but have presented lesions that had seriously crippled their functions. It is, however, in reference to the performance of Battey's operation in the treatment of mental and neurotic diseases that it is necessary to raise a voice of caution and of protest. Let any one consult the reports of the operations for such conditions, and he cannot avoid the conclusion that this operation has in a number of instances been performed when neither the nature of the symptoms nor the benefits secured justified the procedure. It is to be expected that even able and conscientious surgeons will fall at times into errors when resorting to new surgical procedures; yet in some reported cases the operators have been blinded to the best interests of the patient either by reason of too great enthusiasm for abdominal surgery or by reason of too great, and hence unworthy, ambition for personal advancement. In the selection of a case for the operation one must exercise his most conscientious and most intelligent judgment. In reference to this particular resort to Battey's operation the pendulum has doubtless gone too far in the direction of surgical interference; yet to claim that the operation is never indicated in nervous or mental disorders is but swinging the pendulum too far to the other extreme. That some operators have removed the uterine appendages unwarrantably must not lead the physician to the conclusion that the operation is never warranted. In this matter, as in others, the general practitioner, as far as opportunity permits, must acquaint himself with the literature involved, and be prepared to give a fair and unbiassed opinion, so that while protecting his patient from the performance of an unnecessary surgical operation he may not stand in the way of the adoption of the only measure, in some cases, that

can restore health. The field for Battey's operation in psycho-neurotic diseases is certainly very limited. In a given case it is extremely difficult to determine whether the necessity exists for the operation or not. There are no hard and fast rules to be applied in endeavoring to reach a conclusion, and each case must be judged according to its own phenomena. In such cases Battey's operation must not be hastily selected: it can be justifiable only after numerous approved remedies have failed.

I do not intend to discuss those enlargements of the ovary, usually cystic, rarely solid, which lead to what by common consent is known as ovariotomy, but will briefly speak of those changes in the ovaries for which Battey's operation has been resorted to. Oöphoritis and peri-oöphoritis are the two processes which in most cases underlie the morbid anatomy of the ovaries. Acute oöphoritis rarely occurs except as a part of a pelvic inflammation in which either the pelvic peritoneum or pelvic cellular tissue is largely involved. The ovaritis is often masked by the more general pelvic inflammation. Such acute inflammation does not often call for removal of the ovaries, yet occasionally an abscess develops in an ovary, the surroundings of the organ being such that the abscess cannot be safely emptied without a laparotomy, and then the only rational (as it is the safest) method is the removal of the diseased ovary. An abscess of the ovary is the most dangerous form of pelvic abscess, for it is very apt to establish fatal peritonitis by rupturing into the peritoneal cavity, unless fortunately the pelvic tissues have been so matted together as to protect the peritoneum. The removal by laparotomy of an ovary containing an abscess causes the patient to spring almost immediately into a condition of health. Inflammation of the ovary and its surroundings may produce such changes within the ovary or on its external surface as, by reason of pain and numerous reflexes, to lead to invalidism of a permanent character unless the ovary is removed. Under inflammatory action this organ becomes enlarged and is displaced, usually posterior to the uterus, and becomes adherent to it. The ovarian parenchyma becomes so changed as to render the organ's function difficult or impracticable, and painful in either case. Inflammatory lymph-deposits may form over the periphery of the ovary so as to cramp and imprison the organ, and effectually to prevent the escape of the ova even if they should become matured. The tubes are apt to participate in the morbid process and to contribute to the local and systemic disturbances. The oöphoritis or peri-oöphoritis may have originated in an injury, in syphilis, in puerperal inflammation of septic character (frequently after abortion), or it may be after labor at any period. They are frequently sequels of gonorrhœa, and more rarely of an exanthem or of rheumatism. They may be acute in their earlier phenomena, or they may develop stealthily and not be recognized until local changes have become far advanced. It is true that the great majority of such cases, under judicious management and favorable circumstances, recover to such an extent as to place the performance of Battey's operation out of the question; yet there occur certain cases in which, by reason either of dyscrasia, mismanagement, or unavoidable errors in occupation on the part of the patient, the change in the ovaries and their surroundings becomes permanently established. In such cases invalidism becomes fixed throughout the years during which ovulation continues. Pain during and between the menstrual period becomes a prominent and distressing symptom. Locomotion becomes painful, the ordinary avocations of life cannot be followed, opiates are resorted to, micturition is interfered with, the nervous system suffers, and convulsive manifestations may appear. The prolonged interference with rest, sleep, exercise, and nutrition, and the resort to opiates eventually, lead to the development of anæmia and, later on, to probably fatal cardiac, or pulmonary, disease. Doubtless many members of this Society have seen such patients. In such is not Battey's operation, with its probably favorable result, to be preferred to years of invalidism and to the possible occurrence of an induced fatal disease? Must such a patient be doomed to physical and mental suffering? Must she be left to a life of uselessness and of invalidism? Here, too, in the selection of a case for operation, the surgeon must exercise that intelligence which comes from a faithful study of the subject, and he should be conscientious as well as skilful. In a much smaller number of cases the ovaries have been removed by reason of serious symptoms dependent upon a

degeneration in which the ovarian parenchyma seems to have disappeared almost entirely and numerous minute cysts formed. Rarely a condition of cirrhosis of the ovary has been the morbid change. Occasionally a hernia into the inguinal or femoral canal, into the sciatic or thyroid foramen, or by the side of the vagina, has necessitated its removal. Prolapse of the ovary, usually posterior to the uterus, sometimes into the utero-vesical pouch, has seemed to be productive of grave and obstinate symptoms in some instances, and has led to removal of the organ.

Mr. Tait has popularized the removal of the Fallopian tubes for diseased conditions of the tubes themselves. The alterations of the tubes for which their removal has been most frequently resorted to are hydrosalpinx, or accumulation of serum, pyosalpinx, or accumulation of pus, and hæmatosalpinx, or accumulation of blood within the tubes. I have mentioned these conditions in the order of their relative frequency. In either case both extremities of the tube become occluded, and distention has followed, often to the size and shape of a distended piece of intestine, in rare instances to the extent of containing several pounds of fluid.

It has been said that "all the diseased tubes must go to Birmingham;" but Mr. Tait exhibits the tubes he has removed, and also publishes his cases with such data that the most sceptical cannot but be convinced, both as to the much greater frequency of the morbid conditions than was suspected a few years ago, and also as to the advantages of removal.

Occlusion and distention of the tube result usually from a salpingitis itself arising from causes similar in character to those producing ovaritis, the most frequent of which is gonorrhœa. Salpingitis and ovaritis are apt to be associated, and either or both may be but a part of a general pelvic inflammation. Next to gonorrhœa, extension of septic endometritis is the most frequent cause of the salpingitis which precedes the occlusion and distention. The distention may, however, be dependent upon congenital malformation of the tube. The pathological condition of the tube not infrequently leads to permanent loss of health, or, as in the case of pyosalpinx, to fatal peritonitis from rupture of the tube and the escape of pus into the peritoneal cavity. It seems quite certain, from the observations of Mr. Tait, that in some cases of recurring pelvic inflammation the exciting cause is the rupture of a distended tube. Occasionally the tube may empty itself into the uterus, especially if the condition is that of hydrosalpinx. This fact explains the occasional sudden escape of fluid, usually serous, sometimes purulent or bloody, from the vagina.

The symptoms resulting from salpingitis, with occlusion and distention, are very similar to those produced by oöphoritis and peri-oöphoritis. In pyosalpinx the prognosis, both as to life and as to duration of the disease, is more unfavorable than in most cases of inflammation of the ovary, and ranking with ovarian abscess as to associated dangers. The only certain relief for occlusion with distention of the tube is in the removal of the tube. Amelioration of symptoms occurs when the fluid escapes into the uterus, but reaccumulation may take place from time to time, and symptoms may disappear only to reappear probably at short intervals, until invalidism becomes established.

Prior to the performance of laparotomy the diagnosis of diseased ovaries and tubes must frequently rest upon the symptoms alone.

In some cases one cannot by any method of physical examination determine the condition of ovaries and tubes. An exploratory incision through the abdominal wall then becomes essential to the completion of the diagnosis. A simple exploratory incision brings with it exceeding little risk to the patient. Still, in many instances an enlarged, displaced, or adherent ovary can be recognized as such by a careful bimanual examination under ether, and a distended tube can be recognized, especially through the rectum, as an elongated, sometimes fluctuating, tumor. Dr. Lusk reports that in one instance he mistook, in such an examination, an adherent and distended intestine for a distended tube. A laparotomy disclosed the error. His case illustrates the difficulties of diagnosis. Even if the physical examination should not determine the existence of an abnormality of ovaries or of tubes, and yet the symptoms are grave and intractable and point to pelvic disease, an exploratory abdominal incision is indicated. With one or two fingers introduced into the abdominal cavity, the condition of the uterine appendages can be ascertained without ma-

terial risk to the patient. In not a few instances, to wait until one can by ordinary methods of examination determine ovarian or tubal disease will be merely waiting for the abnormality to become so decided as to render surgical interference extremely hazardous or to be leaving the patient go unrelieved. In many cases the diagnosis is easy without exploratory laparotomy; in some cases a positive diagnosis is impossible without it.

When a Fallopian pregnancy has resulted in rupture of the tube, the indication is to make an incision through the linea alba, to ligature and to remove the affected tube, to control bleeding, to clean the peritoneum of blood, and to remove the fœtus. The fact that a few patients recover after symptoms of rupture of the tube in extra-uterine pregnancy should not deter from the performance of this operation. It seems quite certain that the number of such recoveries is very small compared with the number of mothers who die because of the rupture, although statistics are scarcely attainable. Autopsies and the experiences of a few surgeons show that the operation of ligaturing and removing the tube after rupture in Fallopian pregnancy would usually be a very simple procedure. At the period of pregnancy when rupture most frequently takes place—that is, at the second month—the cyst has not commonly formed adhesions, and there is no difficulty in stopping, and in avoiding, hemorrhage. Mr. Tait has operated in nine such cases,—*i.e.*, after rupture of the tube,—with only one death. It is to be hoped that American physicians will not continue to let such patients die without resort to the only rational and now well-established measure of relief.

To arrive at some conclusion as to the results following removal of the uterine appendages in the different diseases discussed, we must consider the prognosis in reference not only to the dangers attending the operation, but also as to the influence upon the disease or the symptoms for the relief of which the operation was performed.

When the appendages are removed because of reflex disturbances, as in epilepsy, there is almost no risk of death following the operation if the ovaries and tubes be free from adhesions. The more nearly normal the appendages, the less the danger of death after operation. Mr. Tait has operated six times for epilepsy, with no deaths; and he states that death ought never to follow such operations, the appendages and their surroundings being nearly normal in character. The operation, under such circumstances, is simple and quite safe in capable hands.

A few reported cases of operation for epilepsy and for mania seem to show the disease cured; in a larger number decided benefit followed; in others no relief. It is too soon to draw conclusions from the bare statistics of such cases, and I shall not submit a statistical statement. Some cases are apparently cured for a while, and the disease then returns; others seem but slightly or not at all benefited for months, and then greatly improve and seem to be recovering. The published reports in most cases do not give the remote effects upon the diseases. I draw, however, the impression that, in a very few judiciously selected cases, a cure of epilepsy or of insanity will follow Battey's operation.

A much larger number of operations have been performed because of inflammation of ovaries and tubes, including under this head cases of distention of tubes with pus, blood, or serum. Operations performed for these conditions bring risks to life varying greatly with the condition of the appendages and their surroundings. The dangers are relatively great when extensive, dense, and vascular adhesions exist, or when pus is present, as in pyosalpinx and in ovarian abscess, as in removal the pus may escape into the peritoneal cavity and fatal peritonitis result. However, Mr. Tait has operated in two hundred and one cases for inflammatory disease, with only ten deaths: a mortality of about five per cent.

The results secured by this skilful surgeon, though more favorable than those of most other operators, yet present, as nearly as can be obtained, the mortality inseparable from the operation. In studying less favorable statistics, the degree of lack of surgical skill becomes a larger element of uncertainty, and it is more difficult to determine to what extent the less favorable result is dependent upon the essential nature of the operation itself.

Hegar states that the mortality following his operations has been about sixteen per cent., and gives the mortality of other operators with whom he is acquainted at thirty-two per cent.

Dr. Mundé has tabulated one hundred and twenty operations by different surgeons, with a mortality of about twenty-two per cent.

When the appendages have been removed because of extensive disease, as occlusion and distention of the tubes, oöphoritis and peri-oöphoritis, with displacement of the ovaries and matting together of the appendages and surrounding structures, ovarian abscess, or Fallopian pregnancy, the effect upon the symptoms has been in nearly all cases very satisfactory, the patient being restored to good health. The benefit, however, is not always immediate, and it may be several months before the symptoms disappear. In some instances the local pains continue indefinitely. In such cases inflammatory action may remain in the pelvis after the removal of the appendages. The pelvic peritonitis or cellulitis so frequently accompanying ovaritis or salpingitis may continue in a chronic form, though usually such inflammation gradually and entirely subsides after the fluxion and hyperæsthesia of ovulation have ceased to recur. In some such unfavorable cases a pelvic peritonitis may have arisen because of the operation, and may occasion a continuance of pelvic distress.

The treatment of uterine myomata very frequently taxes to the greatest extent the skill and perseverance of the physician and surgeon. The most urgent and most distressing symptoms usually are hemorrhage and those due to pressure. The pressure-symptoms, though modified often by the location of the tumor, are usually in proportion to the size and weight of the myoma. The congestion incident to ovulation is usually the element that causes and aggravates the hemorrhage, that determines and stimulates the increase in size and in weight. When the natural menopause has become established, the periodical congestion of ovulation does not occur, and hemorrhage usually disappears, the tumor shrinks, and the pressure-symptoms become less pronounced. It is true such results do not always follow the natural menopause, but they usually do, and are to be expected, excepting in very large tumors probably, and in those of fibro-cystic character. The influence exerted by the natural menopause on uterine myomata led to the removal of the adnexa with the view of establishing an artificial or produced menopause. The removal of the ovaries and tubes for such conditions has been frequently resorted to during the last few years, and doubtless will grow in favor with the profession as the results become more definitely determined. Of course, there are very many patients in whom the symptoms are slight, and the question of the performance of the operation under consideration does not arise. That the mortality dependent upon uterine fibroid tumors, when not interfered with, is extremely low must not too quickly lead one to the rejection of this operation, though somewhat dangerous as to its immediate results, and though it is one rendering sterility certain. An operation which, while it brings a somewhat increased risk of immediate death, brings also great probability that health and a useful life will be substituted for years of illness and relative uselessness, becomes, I take it, not merely a matter of option, but a matter of duty, provided there is no less dangerous method of relief. The adnexa should not be removed either when the tumor or tumors can be removed without great risk, with the écraseur, by traction, and by enucleation, or when the hemorrhage and pressure-symptoms can be sufficiently controlled or ameliorated by other recognized measures.

In the *British Medical Journal* for January 31, 1885, Mr. Tait states that he has removed the appendages for uterine myomata ninety-nine times, with seven deaths: a mortality of about seven per cent.

Mr. Keith, in the same issue of that journal, states that he has removed both ovaries twelve times for myomata, with no deaths. Mr. Keith states that in only one of the twelve cases has menstruation continued, and in that case a portion of one ovary was unavoidably left. He also states that of upwards of sixty cases in which he removed both ovaries for disease, in only one did menstruation return regularly. The cessation of menstruation and the checking of hemorrhage occur, with very few exceptions, after removal of the appendages for myoma. Mr. Tait claims that this result will probably not be secured unless the tubes are also removed, as he believes that the tubes are more concerned in determining menstruation than the ovaries. The difficulties of the operation for myoma vary greatly in different instances, according to the position

of the ovaries, to the twisting of the tumor, and according to adhesions or the approximation of the ovaries to the tumors. These conditions cannot be determined until after the abdominal incision has been made. In some instances of attempted removal of the appendages, it has been found necessary to remove the uterus because of injury done to it during the operation; and in other instances it has been impossible to find the ovaries, they being embedded in the mass of myomata.

Compared with hysterectomy, or the supravaginal removal of the uterus, the result has been greatly in favor of the removal of the appendages. Yet Mr. Keith has reported thirty-eight hysterectomies with only three deaths: a mortality of about eight per cent. But he has removed the appendages for myoma twelve times, with no mortality. Mr. Tait has performed hysterectomy fifty-four times, with nineteen deaths: a mortality of over thirty-five per cent.—to be contrasted with his mortality of seven per cent. after removal of appendages ninety-nine times for myoma. He speaks of hysterectomy as a terrible operation.

The enucleation of large submucous or interstitial myomata is a grave operation, and, were sufficiently extensive statistics ascertainable, a very large mortality would doubtless be presented dependent upon it. It would be better, in some cases in which the symptoms seem to demand enucleation of such large growths, to resort to removal of the appendages, as being less dangerous and more likely to stop permanently the hemorrhage.

In very large tumors and in those of fibro-cystic character the removal of the ovaries seems to be of little, if any, service.

Dr. Battey, in his earlier operations, removed the ovaries through an incision in the vagina. More recently he has resorted to an incision along the linea alba. Unless one is positive that the ovaries are not adherent and not materially enlarged, the incision should not be made through the vagina; and, as the exact condition of the ovaries can rarely be ascertained with certainty before operation, it is best under all circumstances to perform a laparotomy, instead of operating through the vagina, when removal of the appendages is aimed at. It has been found that adherent ovaries and tubes cannot be removed easily and entirely through the vagina, and the operator cannot with certainty control the bleeding which accompanies the tearing up of adhesions.

After laparotomy, the operation of removal is very simple if the ovaries and tubes are nearly normal and are free from adhesions. The operation becomes extremely difficult when the appendages are matted together and are adherent to the bottom of the pelvis. In the hands of surgeons inexperienced in the details of abdominal surgery, the mortality attending removal of the appendages must continue high.

It adds but little, if at all, to the difficulties of the operation, to remove tubes and ovaries together; and as Mr. Tait believes, from his observations, that the tubes are important factors in determining menstruation and in determining what have been considered symptoms of ovarian disease, it becomes prudent to remove the tube with the ovary. It is now generally accepted that both ovaries should be removed, even though the symptoms have pointed to a diseased condition of one side only. In several cases in which an apparently healthy or nearly healthy ovary had been left, the symptoms, after disappearing from the side from which the ovary had been removed, had appeared and persisted on the side of the remaining ovary, and a resort to a second operation for its removal was necessitated.

Proper antiseptic precautions during the operation should be observed; *i.e.*, the operator should have clean hands, clean instruments, clean sponges, and clean ligatures and sutures. Only one assistant directly assisting in the operation is necessary. Corrosive sublimate may be used to render everything aseptic excepting edged tools. The spray has been discarded by most surgeons.

One should not render a woman sterile excepting in the relief of some grave condition. Objection to this operation based upon the fact that sterility is rendered perpetual is in many instances of little weight, as often sterility has already become established by the very condition demanding the removal of the appendages. It seems to be the general testimony that the sexual desire is not usually materially influenced by the operation. The sexual act, often previously painful or impossible, may, after recovery from the operation, be accomplished with entire absence of pain.

In a few instances excessive sexual desire has been noticed after removal of the ovaries: in such cases there have been organic changes in the uterus and its surroundings, and, these being remedied by the operation, the abnormal sexual desire dependent on these organic changes has subsided. After removal of the ovaries the woman's appearance becomes none the less feminine, and the only change it undergoes is that which follows restoration to health. There is no change in the voice.

There are a very few recorded cases in which maniacal or hypochondriacal insanity has developed after the operation,—whether because of the operation or not it is impossible at present to determine.

REPORT ON OPHTHALMOLOGY.

BY ALBERT G. HEYL, M.D.,

Ophthalmic Surgeon to the Episcopal Hospital.

THE INFLUENCE OF LIGHT ON THE RETINAL CELLS.

DR. TH. ENGELMANN has contributed (*Archiv Gesammte Physiologie*) some researches on the influence of light upon the cones and pigmented epithelial cells of the retina. The inner segments of the cones become shorter under the influence of light, but elongated in the dark. When the inner part contains a so-called ellipsoid this does not (or comparatively little) change in form. This is also true of the outer segments of the cones and the rods. It seems that only that part of the inner segments of the cones is actively movable which most resembles protoplasma and which lies between the membrana limitans externa and the outer segment. In this movement the moving part remains always in continuity with its cell-body in the outer granular layer. When it becomes shortened it gains in thickness. When it is elongated it becomes thinner in such a manner that probably no change in volume takes place. In this it corresponds with contractile protoplasma or muscular fibres. The absolute and the relative amount of change in length differ in different animals, and also in the same eye under the same conditions, being sometimes longer, sometimes shorter. The rapidity of the movement is such that in frogs (which have been kept in the dark) the cones previously stretched *ad maximum* after a few minutes of light-exposure are contracted *ad minimum*. The rapidity of movement is evidently of the same order as that of many forms of contractile protoplasma,—*e.g.*, of the pigmented cells of the skin, the contractile cells of the corneal epithelium, and especially the pigment-granules in the protoplasmic offsets of the pigmented cells of the same animal. The pigmented retinal cells undergo essentially the same movements as the cones, but they do not always contract or elongate with the cones. The cones may be contracted *ad maximum* while the pigment-granules have not changed their position, and *vice versa*. It seems that all parts of the visible spectrum can induce these changes. Whether ultra red or ultra violet can do the same is not yet determined. If one eye of a frog be exposed to the light and the other kept in darkness, the cones and pigment-cells in each will be found contracted *ad maximum*,—the only difference in the two being that in the exposed eye the outer segments of the rods were perfectly bleached, while in the unexposed eye they were as intensely tinted as if the frog had not been exposed to light. By repeating the experiments, it was found that this photo-mechanical operation of the pigmented cells and cones takes place with equal strength and at the same time in both eyes when one is exposed to the light, and that when shielded from the light both resume their former position. This, however, occurs only if the brain is uninjured. If this be destroyed, the retinal changes are confined to one eye. The author, therefore, thinks that this reaction must be brought about by nervous connections, and this is through the optic nerves, which, therefore, must contain not only centripetal fibres, but also centrifugal fibres, which act as motor nerves to the cones and pigmented cells. It is possible that in man the fibres of the anterior commissure of the chiasm may act as accessory conductors. Experiments on frogs showed, further, that it is possible, by excluding light from both eyes and exposing the back and posterior extremities to sunlight, to induce the contraction of the rods and pigmented cells as if struck directly by the light. Of course the outer segments of the rods were intensely tinted. One thing is certain, that it is possible to cause a reflex movement in the cones and pigment epithelial cells by the irritation of distant regions of the

body. Finally, the author shows that light is not the only agent which will induce these movements. The same effect as results from light may be induced by tetanizing frogs by strychnia. Curare did not diminish the reaction, nor induce it.—*American Journal of Ophthalmology*, February, 1885.

EFFECT OF COCAINE ON THE POSITION OF THE EYEBALL.

Dr. Baas has observed that after the use of cocaine the axis of the eyeball is directed directly forward. The eye seems involuntarily to assume the primary position. The patient is, however, able to change the position at will. In sleep and general narcosis, the eye has a tendency to rotate directly upward.—*Klinische Monatsblätter*, October, 1885.

THE EYES OF IDIOTS.

Dr. Schleich reports the results of the examination of one hundred and fifty-six idiots. Anomalies of the eye-muscles were seen in ten per cent. of the cases. There was one case of congenital ptosis, ten cases of strabismus concomitans, five cases of nystagmus (one of these had persistent hyaloid artery, and one, a microcephalic patient, had a coloboma of the optic-nerve sheath). The crystalline lens was clear in all the cases. The refraction examination showed a predominance of hypermetropia.—*Klinische Monatsblätter*, October, 1885.

A NEW OPERATIVE PROCEDURE FOR UNRIPE CATARACTS.

Wicherkiewiez reports the following method by which unripe cataracts can be extracted without awaiting the complete clouding of the lens. The danger in such cases is that a large amount of lens-substance is likely to remain within the eye in spite of every effort to remove it. The procedure of Foerster for the artificial ripening of the cataract, according to Wichenkiewiez, when the massage is lightly performed has little or no effect, while if energetically performed it may set up a great deal of irritation, bursting of the zonula, etc. Wicherkiewiez's idea is to remove as much as possible of the lens in the ordinary way, and then to wash out the remainder with an aseptic solution. He has had constructed for this purpose a glass receptacle shaped like a retort. The beak of the instrument terminates in a silver end of a size suitable for entering the anterior chamber; the flask has a vent over which the thumb can be placed and thus the atmospheric pressure regulated. The apparatus is filled with a solution of boracic acid, the end introduced into the anterior chamber, and the cortical washed out from underneath the iris into the pupillary space and into the wound. The author has operated eighteen times in this way, but considers this number too small to tabulate, but thinks the procedure will at least prove an advance in the antisepsis of the anterior chamber.—*Klinische Monatsblätter*, November, 1885.

ADHESIVE STRIPS OF GELATIN FOR CATARACT-EXTRACTIONS.

Galezowski, who advocates a corneal cut in cataract-extraction, suggests the use of gelatin adhesive strips for the closure of the wound. Convinced that corneal suppuration in many cases, at least, is due to infection with micro-organisms, and having operated with antiseptic spray and bandages, he conceived the idea that if the wound were sealed by an impervious covering the infection would be prevented. He employs for this purpose very smooth and soft gelatin strips about one-half millimetre thick. This strip contains a small amount of corrosive sublimate, and is moistened with a cocaine solution that it may be more easily applied. The strip is dipped in hot water and applied with a forceps to the wound, the lids closed over it, and a bandage applied. The strip melts gradually, and at the end of eight to twelve hours has disappeared. The complete coaptation of the parts takes place rapidly, and Galezowski has thus been enabled to leave the eye unbandaged at the end of the fourth or fifth day. He has employed the strip thus far in nineteen cases of extraction, in an operation for keratoconus, in an iridectomy for ulcer of the cornea. One of the cataract cases was complicated with suppuration of the lachrymal sac. At the desire of the patient, the extraction was made without previously curing the sac-inflammation. The case did so well under the gelatin strip that the bandage was removed on the fourth day.—*Centralblatt für Augenheilkunde*, November, 1885.

NEW INSTRUMENTS.

Agnew's Bident.—This is essentially two cataract-needles six-eighths of an inch

in length, joined together at one end, making a fork-shaped instrument,—the prongs, represented by the needles, being about one-eighth of an inch apart. The instrument has been devised for the removal of lenses dislocated into the vitreous. The needles, in the grasp of a needle-holder, are entered into the vitreous posterior to the lens, and by rotation the lens is brought forward into the pupillary space and the counter-puncture then made through the sclerotic. The lens, resting on the prongs of the bident, can be removed through the corneal section.—*Trans. of the American Ophthalmological Society*, 1885.

Discission Instrument.—Heyl describes an angular needle for operating on secondary cataracts. It is, essentially, the Hays needle bent at an angle, the principle being that, instead of acting by a pure lever-motion, the movement which rotates the needle communicates a cutting-motion at the same time. Practical experience has confirmed the utility of the instrument. —*American Journal of the Medical Sciences*, October, 1885.

An Electric-Light Ophthalmoscope.—Dr. Dennett has described an instrument in which the lamp (of about three-quarters candle-power) is introduced into the handle of the ophthalmoscope. This handle is hollow, and the light, proceeding through the tube, strikes the mirror at right angles, and is thus reflected into the patient's eye. —*Transactions of the American Ophthalmological Society*, 1885.

THE GONOCOCCUS OF NEISSER.

The micro-organism discovered by Neisser in gonorrhœal discharge is the subject of a monograph by Dr. Ernest Bumm. The following are some of the results based upon the examination of vaginal discharges and the conjunctivæ of newborn children. In the puerperal state an enormous development of the coccus takes place, more especially in women with chronic cervical gonorrhœa, which generally gives rise to so little disturbance that its nature is recognizable only by the microscope. In the conjunctiva the coccus is generally associated with other forms of micro-organisms. In simple conjunctival catarrh the coccus is absent. The coccus cannot force its way through an intact pavement epithelium. When a tissue in which both pavement and cylindrical epithelium exist together is infected, the line of demarcation between the two is marked. Study of the conjunctiva shows that the coccus forces its way through the epithelium into the underlying tissues; at the same time large numbers of white blood-corpuscles escape from the enlarged capillaries, and the epithelium is to a large extent destroyed. The cocci increase in numbers, and the second or suppurating stage is reached. On the fourth day the regeneration of the epithelium begins, and it is completed in about ten or twelve days. Dr. Bumm has succeeded in cultivating the coccus, and from a pure culture inoculated the healthy urethra of a woman, with the result of developing a typical gonorrhœal urethritis. Inoculation with gonorrhœal discharge freed from the coccus gave a negative result.—*Centralblatt f. Augenheilkunde*, November, 1885.

MYXO-SARCOMA OF THE OPTIC NERVE.

Prudden reports the following case. Carrie L., æt. 12, of good health and without history of constitutional taint, presents herself with exophthalmus of the left eye. The conjunctiva is hypertrophied and red, the cornea hazy. The pupil, moderately dilated, responds very little to light. A tumor can be felt behind the eyeball. Ophthalmoscopic examination shows a pink reflex, retinal vessels much diminished in size, optic disk very white. There is no perception of light. According to the history, the tumor has been growing for at least six years. The tumor was removed with the eyeball. During the operation the sheath, which seemed to be distended with fluid, was punctured, and a yellowish serum escaped. The tumor was pulled forward in order to remove every vestige of it. Troublesome hemorrhage followed, perhaps from the recession of the artery. The patient vomited a good deal, and this was accompanied by fresh flow of blood. The hemorrhage was finally stopped, but, after a lapse of five hours, set in with such violence as almost to lead to a fatal result. The tumor proved to be a myxo-sarcoma.—*Archives of Ophthalmology*, 1885.

BLINDNESS FOLLOWING ATTEMPTED TOOTH-EXTRACTION.

Swan Burnett reports the following case. A colored man, æt. 35, was operated on for cataract of the right eye with partial success. The left eye had perfect vision

for ten years later. About this time he went to a dentist for the purpose of having the left upper canine tooth extracted. Persistent but vain efforts were made to remove the tooth. The same evening the left side of the face began to swell, and the eyelids closed over the eye. Fever set in; abscesses formed near the inner canthus, the forehead, and cheek. When the swelling subsided, the eye was blind. Examination showed a white nerve and a number of emptied vessels resembling white lines running over the retina. The appearance of the fundus resembled very closely that seen in atrophy after erysipelas.—*Archives of Ophthalmology*, 1885.

THE ELECTRO-MAGNET IN OPHTHALMIC SURGERY.

The following is extracted from the review of Hirschberg's book on this subject in the *Archives of Ophthalmology*, vol. xiv. p. 426. The instrument used by Hirschberg is a magnetic machine, with zinc-carbon elements in a glass jar holding one litre. He renews the fluid from time to time, and always tests the energy of the current before using it. There is no need of the enormous machines proposed by Voltolini. Voltolini asserts that the click of the iron striking the magnet cannot be heard; but Hirschberg asserts that he has repeatedly heard it. Comparison of the magnetic extraction of iron from the lens with the old method shows that the former offers no special advantages over the latter, except that with the magnet the foreign body never falls into the vitreous. The removal of iron from the vitreous is the most important for magnetic extraction in ophthalmic surgery. The extraction may be made either through a meridional cut in the sclera or by a corneal section after extraction of the lens or after capsulotomy. A piece of iron is small for the vitreous chamber when it weighs from twenty-five to thirty milligrammes, and with such a piece of iron we may obtain perfect success, even at a late date. It is moderately large when it weighs fifty to one hundred and fifty milligrammes, and then only an early operation is likely to be successful. When it weighs from two hundred to five hundred milligrammes, the most prompt extraction cannot restore vision, and even the preservation of the eyeball is doubtful.

It is difficult to define the indications for operating. If we see a patient in the first stage, with a small piece of iron in the vitreous, it is best to operate without delay. If a scleral section must be made, we must etherize the patient,—the pain in removing the foreign body is said to be excruciating,—and choose a spot rather downward and outward than downward and inward. If an equatorial section be made, there is danger of collapse and total destruction. In making the section, a Graefe knife is plunged through the sclera several millimetres deep into the vitreous, and the scleral incision is enlarged to about six millimetres in length. The magnet is then introduced and allowed to remain several seconds, and then withdrawn. The danger of sympathetic ophthalmia is slight after using the magnet.

Hirschberg adds, "If, in the long list of extractions of iron from the vitreous with the magnet which I have performed in the last five years, I have succeeded twice in obtaining excellent vision, once a remnant of vision, and twice in preserving the shape of the ball, the difference in favor of this method will be more marked when I say that in the first ten years of my practice I never succeeded a single time in saving a trace of sight when I attempted the removal of iron from the vitreous by purely mechanical means." Hirschberg also gives an instance of a minute piece of iron being removed from the lens by a magnetized cataract-knife; and, in cases of minute chips in the lens, the effect of magnetized instruments is to be tried before resorting to the magnetic battery.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CLINIC OF J. M. DA COSTA, M.D.,

Professor of Theory and Practice of Medicine in the Jefferson Medical College, Attending Physician to the Pennsylvania Hospital, etc.

MALARIAL TOXÆMIA—ENLARGED SPLEEN TREATED BY ERGOT.

GENTLEMEN, — The patient before you is one whom you have previously seen. As he is about leaving the hospital, I thought it would be of interest to you to note the progress of the case as well as the results of treatment. He was before you on the 7th day of last month. He is the one who had the enormously-enlarged spleen,—whose system was saturated with

chronic malarial poisoning. He had, as you may recall his history, irregular chills for three months preceding his coming into the wards, on the 21st of last October, and even after his admission he presented at times these irregular evidences of malarial infection. He was treated chiefly with quinine given in amounts not exceeding sixteen grains daily, and occasionally with mercurials to relieve a tendency to constipation, but he did not improve greatly. It is true that the manifestations of malarial poisoning, in so far as the outbreaks of chills were concerned, disappeared, but the enlargement of the spleen was very little influenced; and, in addition to this, I find, in a note made on the 7th of last month, that "he has a sallow skin, yellow-tinged conjunctiva, and his liver is slightly enlarged; and the spleen extends from the sixth rib nearly to the ilium, and horizontally the dulness extends to within three inches of the median line." There was also some dyspnœa, and a trace of albumen in the urine. There was no indication of disorder of the heart. Upon examination of the blood no change was detected in the usual proportion of the white corpuscles, but there was an actual decrease in the red of about one-half. Therefore it was a case of anæmia of splenic origin due to the malarial poison with beginning leucæmia. I decided then to give him ergot,—a plan of treatment I originally employed several years ago and have found very successful. The quinine was reduced to tonic doses of six grains daily, and the fluid extract of ergot was given, a drachm three times a day.

The man has since then steadily improved. His tongue is clean, the lips are of good color, his conjunctivæ are clear, and his bowels are regular. The liver-dulness now has decreased to normal; but what will interest you most is the size of the spleen. The percussion-dulness, which formerly extended across to the ilium, I find this morning is not more than an inch below the border of the ribs; the upper limit of dulness begins on a line drawn two and a half inches below the nipple, at the lower border of the sixth rib, and extends to about two fingers' breadth below the margin of the rib in the left axillary line. Transversely, the dulness does not now begin until about six or seven inches from the median line, so that the spleen has been reduced to nearly its normal conditions. It would be still considered a slightly-enlarged spleen in a person otherwise healthy, but it is only a little larger than normal, and we say that practically the spleen has been restored to its normal size. The temperature throughout has been about normal, except during the chills. The blood was again examined two days ago, and it was found that the proportion of red and white corpuscles had been restored to the normal; in other words, the red corpuscles had doubled in amount.

That the cure in this case may be attributed to the ergot, there can be no doubt. It was not due to the quinine, because that had been given before, and in large doses, without producing the same effect.

How is the ergot best administered? I first began to use it hypodermically, but the patient objected, and finally refused to allow it to be given in this way. He then was given half a drachm thrice daily by the mouth, and in a week the dose was increased to a drachm of a trustworthy fluid extract, and his stomach has borne it well.

I will not say that I prefer the administration by the mouth: hypodermically it acts more quickly, and when I began my observations some years since I used it in this way. But I soon found, especially in children, that the internal method of administration was also efficient, although slower. Therefore I adopted the rule to use ergot hypodermically in adults when a rapid result is desired, and where time is of less importance to give it by the mouth. How does the ergot act? I think by a constringing effect upon the blood-vessels: the spleen being a very vascular organ, the ergot acts upon its blood-vessels, reducing their size. What strikes us here is the interesting physiological fact that, under the action of the ergot upon the spleen, the blood has become normal. We gave him no iron. As his spleen came down in size the blood improved, although since admission he has had none of the remedies which are supposed to act upon the blood and increase the number of red corpuscles.

The patient is about to leave us, and the question now before us is, Shall he continue his treatment? I do not think it really necessary, but he may take the following, chiefly for its strengthening effect:

℞ Cinchonidiæ sulphatis, gr. ij;
Extract. nucis vomicæ, gr. 1/8;
Rhei, gr. j. M.
Ft. pil.

He shall take one of these pills morning and evening. The effect will be tonic, and at the same time the pills will keep the bowels in a soluble condition, and thus prevent anything like abdominal fulness. If he will pay proper attention to his diet, and live in the open air, I believe he will remain in health, to which he is now restored; so that it will not be necessary to continue this treatment for a very long time.

A VERY SEVERE CASE OF CHOREA SUCCESSFULLY TREATED WITH HYOSCYAMINE.

I shall next show you a case which was one of the worst cases of chorea that I have ever seen in this hospital, or, indeed, anywhere else, but there is very little for you to see of the symptoms this morning, the boy has so much improved. The patient I am about to exhibit to you, and whose case I propose to make the subject of some clinical remarks, is a boy about 11 years of age. He has always been pale and weakly, and his friends, when he was brought here, said that he was always a very nervous child. Four weeks before the date when he was admitted (on the 14th of last month) he had an attack of acute rheumatism, which involved all the larger joints of his body. The rheumatism lasted about three weeks, but as it declined choreic symptoms began to be manifested. His hands and arms were first affected, and afterwards his legs.

When admitted, he was actually unable to walk; he was even unable to feed himself: in truth, the poor boy seemed in risk of starvation. He was wretchedly weak and emaciated. He could perform no co-ordinated movements with his arms or legs, and unless there was always somebody about to give him a drink of water and food he would have perished. This was not due to actual want of power in the muscles, but to the impossibility of performing any voluntary act requiring co-ordinated movements; yet when food was placed in his mouth deglutition was readily accomplished. When he came here he could not speak, he could not articulate a word. He could not put out his tongue, although he could open his mouth and move his jaws, but he could not ask for food. His expression was that of an imbecile, and he was reduced to a mere shadow. Indeed, I fear that you will hardly believe me, when you see him now, that he is the same boy whose history you have just heard.

When I first saw him, his arms and legs were constantly moving, both sides being equally affected. No power of grasp existed in his hands, though sensation did not seem impaired. He complained of pain when he was pinched. The patellar reflex was normal, and not exaggerated. No marked change in the electrical reactions was observed. His pupils were very much dilated; his pulse was only fifty per minute, and rather weak; there was a systolic mitral murmur heard at the apex. These are the main points in the case; but allow me to mention one or two more, so as to bring the case fairly before you as he was, before seeing him as he is. These involuntary muscular movements did not continue at night, when he was asleep. His urine has been examined, but neither albumen nor sugar was detected. His bowels tend to constipation. We detected the mitral murmur shortly after admission.

Gentlemen, here was a case of unusually violent chorea. There was general loss of power from want of control over the muscular movements. It seemed that unless we could give this boy rest he must rapidly perish. I have already told you that he was unable to feed himself, or even to express his wants.

The ordinary remedies for chorea act slowly; arsenic, though one of the best of our therapeutic agents for this disorder, acts slowly; it takes time, and the loss of time here might be fatal. I then recalled a case of tremor which I had seen rapidly influenced by hyoscyamine, the active principle of hyoscyamus niger. I concluded to try it here. I ordered him to take one-two-hundredth of a grain to begin with, a decided dose for a boy of his age; but, not finding any marked influence, I concluded that it would be advisable to increase the dose to the one-hundredth of a grain, given three times a day. Now the effect was admirable. From the first few days the boy began to improve, and at this time he had some dryness of the throat and wanted his mouth frequently moistened. He soon became brighter in his mind; he took more interest in what was going on; he moved voluntarily in bed, and tried to help himself

to food. His voice also returned, and he left his bed and began walking around the ward. After this his recovery was rapid and uninterrupted. He has had no other treatment than the hyoscyamine, and he has now so much improved, though he is still somewhat pale, that he may be looked upon as having recovered. He is sitting quietly; he has power over his hands, both in co-ordination and in grasp, although his grasp is still a little feeble. He walks and stands now without falling. His pupils are dilated, although not much.

The systolic apex-murmur persists: it is a chronic mitral regurgitant murmur. In every other respect the boy is nearly well.

Now, there are one or two points of clinical interest to which I would like to call your attention: first, some points which have nothing to do with the treatment; and, secondly, some which bear upon the treatment.

In the first place, this attack of chorea was clearly of rheumatic origin. It came on at the end of an attack of acute rheumatism. It is true that the boy was previously feeble and ill nourished, and that he was regarded as a nervous child; but the association of chorea with rheumatism is too close a one for us to regard it here as a mere coincidence. You can generally trace, in a case of chorea, a strong rheumatic element, either inherited or acquired. Occasionally you will get hold of a case just like this one, which I could easily duplicate from my experience In this form, before the patient has left his bed or his attack of rheumatism is clearly over, the chorea is manifested: which makes the connection still closer. Now, it has been thought that there is an embolic process at work in the smaller blood-vessels of the motor centres in the brain and spinal cord; small vegetations which are formed upon the valves are washed into the arteries supplying the motor tracts, especially the corpora striata, and the subsequent disturbances of nutrition give rise to the irregular, unco-ordinated muscular movements. This is a plausible and ingenious theory; yet I cannot think that it is sufficient to account for all the features of the disease. There must be some want of stability of the motor centres, independent of the coarse lesions resulting from embolism, the evidence of the existence of which, moreover, is not complete, and which is certainly not constant.

You noticed the extraordinary extent to which the manifestations of chorea have been carried in this case. He had no voluntary control over his muscles, and at the same time his mind seemed to suffer: he was almost an idiot. When admitted, his temperature was 98¼°: therefore the attack of rheumatism was over, and these symptoms were not due to a fresh outburst of the rheumatic affection. The want of power in these muscles must also be taken into consideration, as showing a close relation between chorea and paralysis.

Now, coming to the question of treatment, the influence of the hyoscyamine, which was suggested by analogy from the treatment of tremor, was here strikingly manifest. I have told you that the dose was increased from one-two-hundredth of a grain to one-hundredth of a grain without any bad effects; but when he was taking this quantity he complained of some dryness of the throat, although it never was so severe as to require us to reduce the dose again. On the 21st of last month the daily amount was reduced to two granules instead of three. It was finally discontinued two days ago. Now he is perfectly steady and can control his movements; his tongue is clean and he has a good color; he is gaining flesh: indeed, he may be considered as well.

Did the hyoscyamine produce the striking effect, or did the rest in the hospital do it? That rest is good in all and can cure many cases of chorea, is admitted; but the improvement here was too sudden—coming on in three or four days—and too great to be attributed entirely to the good nursing and the food which he received since he was admitted. It is claimed that hyoscyamine is a valuable antispasmodic and exercises a remarkable control over muscular movements; also that with the control of the movements the condition of the muscles is improved and all the functions increased. Even the blood has improved; for, though he is still anæmic, he is not so much so as he was. Within a week after beginning the treatment he was out of bed and walking around, but not so well as at present.

What shall be given further? Will not the condition remain? Not necessarily; for all the irregular muscular movements have ceased. He can take, however, for his anæmia, the elixir of the pyrophos-

phate of iron, a drachm three times a day, and stop the hyoscyamine as having accomplished its purpose.

RHEUMATIC MYOSITIS OF MASSETER MUSCLE.

I will now show you another case of interest. This one you will see at its height before any treatment has had much of an opportunity of influencing it. He occupies Bed No. 2 in the Men's Medical Ward. He states that he had never been subject to acute articular rheumatism. He is 26 years of age. Two years ago, he says, he had a peculiar attack, during which the right cheek was swollen and painful, and he remembers that he was unable to open his mouth: this lasted for one week. He had at that time several bad teeth, and he attributed the attack to them, although the swelled face was not associated with toothache, nor could he find any soreness in the teeth, nor indeed any change in them from what they had been for some time before. He then got well, and had no further trouble with his face until the present illness began.

Four days before admission (he came in on the 8th of the month), he had been exposed to cold, and at once the right cheek became swollen and painful,—in other words, very much the same kind of an attack as that of two years before. When admitted, he could scarcely open his mouth, and could not open it sufficiently to protrude his tongue when requested. The right cheek was tender, swollen, and painful upon pressure. There were points of tenderness at the articulation of the lower jaw and along the ramus of the right side; but the teeth were not tender. Although we found two which were decayed on this side, yet they had given no trouble for a long time. The right masseter muscle was found to be hard, rigid, and painful upon pressure. His temperature was 99°; his urine was 1022, acid, and did not contain albumen.

Now, gentlemen, here we had a very striking case; I speak of it as it was only a few days ago. There was great swelling, hardness, and tenderness of the right side of the face, which has somewhat subsided. He can now open his mouth a little, but complains of pain at the angle of the jaw. The masseter muscle is still rigid, but less so than at the time of his admission. He can now swallow, and the symptoms are passing away.

This case might well introduce an interesting discussion. When he came in, there was nothing to be seen in the mouth, the gums showed no signs of recent inflammation, and no tenderness was evoked upon bringing the jaws forcibly together. He had no distinct fever, but was feverish and restless at first; this has all gone. His tongue can now be slowly protruded; it is not coated. His bowels are regular.

I regarded this case as a peculiar manifestation of acute rheumatism, which here attacked the masseter muscle. This would produce rigidity and the difficulty in mastication already described. The only question in the diagnosis is with regard to the teeth; but I do not think that they have anything to do with it. The attack came on suddenly; it was very marked; and the teeth were not directly affected. I think we must look upon it as a local manifestation of a rheumatic condition of the system.

The only thing that we have done in the way of treatment was to administer hypodermic injections into the affected muscles of solutions of atropine and morphine, from which I have already obtained such good results in the treatment of spasmodic wry-neck. Under these the disease is rapidly yielding. He receives one-sixtieth of a grain of atropine and one-sixth of a grain of morphine once a day. He has had only two injections; but he has begun to improve. Dryness of the throat he has not complained of, but his pupils are seen to be a little dilated. No effect upon the pulse has been shown. The dose will be increased to the one-fiftieth of atropine, accompanied by the one-sixth of morphine, which to some extent counteracts the effects of the former. This will constitute the local treatment; while to remove the rheumatic element I will order him to take salicylate of sodium, fifteen grains every three hours, until he takes six doses, so that he shall take daily one drachm and a half. It can be mixed with a little spirit of lavender and mint water.

℞ Sodii salicylatis, gr. xv;
Spiritus lavandulæ comp., ♏x;
Elixir. aurantii, ♏xxx:
Aquæ menthæ pip., ʒj–♏xx;
Pulv. acaciæ, gr. j. M.

Sig.—To be taken every three hours until six doses have been taken in the day.

Continue the hypodermic injections.

TRANSLATIONS.

Tremor as a Symptom of certain Cortical Cerebral Lesions.—In a recent series of experiments conducted in the laboratory of Vulpian, the method of causation of some forms of tremor was especially studied by Dr. Gasternatzvy. He had previously found that muscular trembling analogous to that observed in the human subject in multiple sclerosis (*sclérose en plaques disséminées*) appeared in animals when the antero-lateral columns of the spinal cord were injured, which in health usually transmit the impulses determining voluntary muscular movements. Proceeding to investigate the production of tremor when the spinal cord was not invaded, he found that under the influence of chloroform the excitability of the cerebral cortex diminishes gradually, and as the movements under the electrical stimulation become weaker, muscular trembling appears. He therefore attributed the muscular tremor to weakening of the psycho-motor centres, especially since he found that the force of the faradic current had to be materially increased in order to obtain the same degree of response as before the anæsthetic was used.

These experiments seemed to the reporter to explain certain clinical facts, and to locate the causation of this form of tremor in the gray substance of the cortex of the hemispheres,—for instance, the tremor observed in patients afflicted with general paralysis of the insane. In fact, in this disease the essential anatomico-pathological lesion consists, in part at least, of a periencephalitis, and this leads to atrophy of the cortex of the hemispheres, with loss of the nervous elements and proliferation of connective tissue, production of pigment and of drops of fat. It is probable that these products remain to play the part of irritants to the other nerve-cells of the cortex, which have not as yet lost their functions. Besides, the paralytic tremor (one of the most important signs of this disease) itself furnishes some signs which show its dependence upon the gray matter of the cerebral cortex. First, since this trembling is general, and exists in all the voluntary muscles of the body, it shows that the lesion which provokes it exists in a part of the nervous system with which all these muscles are in communication, and the gray matter of the cortex of the hemispheres is precisely this region. Secondly, the paralytic tremor always accompanies the other symptoms, which depend incontestably upon certain lesions of the cortical gray substance,—for example, the symptoms of progressive dementia, analgesia, epileptiform attacks, and vaso-motor and trophic phenomena. Thirdly, at the commencement of the malady the tremor is scarcely discernible during slight, delicate movements, which are ordinarily the most complex and the best co-ordinated, and as the disorder gradually increases the tremor follows, until finally, in the last stage of the disease, the tremor leads to complete paralysis of all movements, either psycho-motor or voluntary. Consequently, there exists a relation between the paralytic tremor and the other symptoms of the disease on the one side, and upon the other with the progressive development of the anatomico-pathological process of the gray matter of the hemispheres of the brain, which constitutes the essential characteristics of the malady.—*Le Progrès Médical.*

Leprosy.—Dr. R. Suzor, of Mauritius, contributes to the *Progrès Médical* (No. 14) some interesting points with regard to leprosy. As the question of the contagion of this disease has recently been discussed, he brings forward the results of some personal researches in the Mauritius, Réunion, Sandwich Islands, and British Guiana. He first notes the great increase in the number of cases occurring in the ten years after the institution of Chinese immigration. Previous to the year 1848 it had been very rare or unknown; in 1858 it had increased to such a degree that one-tenth of the population was leprous, reminding him strongly of the epidemic in Europe of leprosy in the Middle Ages after the return of the Crusaders. In Guiana the contrast is still more striking. Leprosy was unknown either among the natives or white settlers prior to the introduction of slavery. Among the negroes there were some afflicted with leprosy. Isolation was practised, and the disease was limited strictly to the blacks; but in 1831 more than four hundred were established in a settlement on the banks of a river near which some Indians lived. In 1842 a large proportion of these natives were affected; but it was only those belonging to the affiliating tribe to whom the disease had extended, and especially had it oc-

curred in children of this mixed parentage. At the present time two per thousand of the entire population are leprous, and the whites and mulattoes furnish their share, as well as the negroes and Indians.

Several cases are cited which acquired leprosy by consorting with lepers; and in one instance two children of healthy parents became leprous apparently as the result of having been vaccinated with lymph taken from a child belonging to a leprous family. This case was believed to furnish conclusive proof of the communicability of the disease by vaccination. A number of cases in children and adults are cited to illustrate the hereditary transmission of leprosy. The question is asked, May an affection which propagates itself by heredity, by contact, sexual intercourse, and vaccinal inoculation, and which makes its appearance most often upon the uncovered portions of the body, be considered as contagious or not? As well ask the question of syphilis, which is far from being contagious at all periods, and does not always lead to hereditary accidents. Further investigations will be made in order to isolate and cultivate the bacteria of leprosy in human serum, and to compare with it the growth of the bacillus of tubercle in the same medium. If pure cultures can be obtained, an opportunity may occur of making inoculation-experiments.

Etiology of Dupuytren's Contracture.—A peculiar case is reported by Dr. Lange, of Stettin, of a woman, who for years had had a contracture affecting the ring-finger of each hand to such a degree that the finger remained flat upon the palm when the others were extended. Both ring-fingers were equally affected. An apoplectic attack supervened, with left hemiplegia, and from that moment the affected finger became fully extended and remained so; and of the folds of the skin of the palm, which before were so marked, only traces remained; while the other hand retained its former condition until death occurred, several years later.

This case would support the view (which is favored by the symmetrical character of the affection in both hands) that the disease has its point of origin in the cerebral nervous system, and therefore disappears in paralysis. A local disease of the muscle, tendon, or peripheral nerves would not disappear so rapidly after the onset of the hemiplegia. The surgical indication is to weaken or suspend the nerve-supply, which will affect the other fingers less than the contracted one. Nerve-stretching or excision of the nerve-trunk might prove of service.—*Archiv für Path. Anatomie und Phys. und für Klin. Medicin*, October 7.

Pneumonia treated with Massive Doses of Digitalis.—Petrescu, of the Military Hospital at Bucharest, reports remarkable success in the treatment of acute pneumonia from the administration of large doses of digitalis, given in the form of recent infusion. His conclusions, based upon observation of three hundred and fifty cases, are as follows:

1. Digitalis produces antiphlogistic and direct effects only when given in appropriate dose.

2. This dose is from four to six grammes (℥j–jss) given during the twenty-four hours, and continued for several days. In this way he has given as much as twenty grammes (℥v) inside of three days.

3. The treatment of pneumonia by digitalis is the only method at present of reducing the mortality of the disease to a minimum.—*Le Progrès Médical*, and *Deutsche Med. Zeitung.*

Precautions against the Spread of Hydrophobia.—A veritable epizoötic of hydrophobia having occurred in the department of Var, in France, it was made the subject of a report to the French Academy by Dr. Chassinat, of Hyères. M. Leblanc thereupon called attention to the law which compels owners of dogs or cats to destroy them on the first appearance of symptoms of madness, and requires local authorities to capture and kill all unregistered dogs found at large. It also forbids the sale for food of the flesh of animals which have been bitten by a mad animal until the expiration of at least six weeks. The Academy passed a series of resolutions calling upon the government to render uniform, generalize, and enforce the laws, and to postpone the abolition of the law forbidding empirics to treat animals affected with contagious diseases until July, 1887. M. Leblanc estimated that there are at least thirty thousand street-dogs in the city of Paris alone, which constitute a standing danger of the spread of hydrophobia.—*Journal d'Hygiène.*

EDITORIAL.

THE ACTION OF THE COUNTY MEDICAL SOCIETY.

AT the stated meeting of the Philadelphia County Medical Society held on the 6th instant, for the purpose of electing officers, the regular nominations for delegates to the State organization and the American Medical Association were set aside and a new ticket introduced and elected by a proceeding without a precedent in the history of the Society.

Now that the meeting is over, and we review its proceedings, we feel that no one who was present can escape a sense of mortification at the disorder which prevailed during the discussion, if not of regret for the results of the ballot. It is true that, by the concerted action of one hundred and fifty members, the Society (whose entire membership is nearly five hundred) finds itself with a bad precedent established, and with a lively factional quarrel in prospect.

Let us see what was gained by this revolutionary procedure. Those having the matter in charge succeeded in having declared elected delegates whom no one will pretend to be better or more representative men than those discarded. They also had passed a resolution disapproving of the course pursued by the American Medical Association at New Orleans, and instructing the delegates to "endeavor to secure such modification of that action as may best conduce to the re-establishment of professional harmony and to the success of the Congress." On the other hand, they have raised a storm of feeling in the County Society which must inevitably react in the end upon the leaders of the movement, and thus inaugurated a state of affairs which all should deprecate as threatening the best interests of the Society.

The evident intention of those who substituted, in this hasty and irregular manner, an entirely new list of delegates (some of whom were not even members of the Society) was avowedly to send only those who would endeavor to carry out the plan set forth at a meeting of a few members of the profession interested in the International Medical Congress, held quite recently in this city,—to wit, "that the present Executive Committee should unite with the Original Enlarged General Committee, and recommence" (*sic*) "the organization *de novo*."*

We have no hesitation in declaring that such a hope is futile; it can never be fulfilled. The American Medical Association and the profession will not invite the members of the original Committee again to assume control of the organization of the Congress. The probable result of such a course is apparent from their record. Thus, on May 8, 1884, that Committee reported the following resolution:

"That it shall be the duty of the Committee to extend, on behalf of the Medical Profession of the United States, to the International Medical Congress about to meet at Copenhagen, a cordial invitation to have the International Medical Congress meet at Washington, D.C., in 1887."†

This resolution was adopted, and the sum of four hundred dollars appropriated by the Association to meet the preliminary expenses of this Committee, and the money was afterwards paid by the Treasurer.

On April 28, 1885, the Committee reported to the Association that they had "met at Copenhagen during the meeting of the International Medical Congress, and presented the invitation, which was accepted."‡ To this was appended a

* See page 223, *ante*.

† Journal of the American Medical Association, vol. ii. p. 565, 1884.

‡ Ibid., vol. iv. p. 549, 1885.

"Preliminary Plan of Organization," that was discussed by the Association, which declined to endorse or accept their appointments, as they had exceeded their authority. The Association thereupon expressed its disapproval of their action by appointing a new Committee, but courteously continued them as a part of the Enlarged Committee. From this action the original Committee rebelled; and now a few of its members decline to participate in the efforts of the remainder, who are striving to make good the cordial invitation accepted at Copenhagen.

The question naturally arises, Is the course of these physicians loyal to the profession that intrusted them with a mission?

THERAPEUTICS OF INFANTILE PARALYSIS.

THE treatment of essential paralysis in childhood is too often disappointing and unsatisfactory,—disappointing to the parents because, on account of the abrupt onset, they are not prepared to appreciate fully the gravity of the disease, and unsatisfactory to the medical attendant, who may find that in spite of his efforts an interesting and attractive child has become the subject of a terrible deformity and is possibly crippled for life. Routine treatment in such cases, too, is usually inefficient, and children are allowed to grow up with withered, shortened limbs, dangling joints, and consequent disfigurement. A plan of treatment, therefore, which was formulated recently by Dr. William Murrell, in a lecture delivered upon this subject at the Westminster Hospital,* deserves serious consideration, since it is based upon an experience extending over six years, during which period notes were taken of fifty-six cases of this disease, and in every instance in which the treatment was carried out actively and systematically the lecturer declared that "the best possible results were obtained." This expression is qualified because of the fact that most of them were not acute cases, and that some, at least, were of many years' standing, and clearly unfavorable for treatment.

The method pursued is, in brief, during the first or febrile stage, rest, aperients (Friedrichshall water is excellent for this purpose), milk diet (peptonized if necessary), with small doses of tincture of aconite (one-fourth of a minim) given every hour until three doses are taken, and every alternate hour for three more doses, then repeated every three or four hours until the temperature is normal. Convulsions, if present, may require bromides by stomach or rectum. In the second stage, the child is to be allowed to get up, and have a liberal diet. Small blisters or tincture of iodine should be now applied to the spine, and physostigma given in granules (of one-fiftieth of a grain of the extract), beginning with one three times a day, and increasing gradually until one is taken every three hours.

This should be kept up persistently for many months; but after the first six weeks it may be combined with small doses of phosphorus (one-two-hundredth of a grain or less). As soon as the acute symptoms have subsided,—that is to say, at the end of three or four days from the onset of the attack,—massage should be commenced and carried on systematically by an experienced and expert hand. Special stress is laid upon this point, for upon the skill of the *masseur* or *masseuse* will depend to a large extent the success of the treatment. It is to be applied not only to the spine and back, but also to the paralyzed limbs. The methods found most applicable are *effleurage*, *friction*, *pétrissage*, and *tapotement*. The number of sittings should vary from one to five daily, not too prolonged: these must be kept up for at least six weeks, and they may be required to ex-

* Lancet, December 26, 1885, page 1177.

tend to six months or more, with occasional intermissions. Galvanism to the spine and either the galvanic or faradic current to the muscles (applied to the motor points) is a valuable accessory; and likewise baths of sea-water, or pine-baths. Cod-liver oil, extract of malt, and syrup of the phosphates, or of the hypophosphites, are also capable of rendering valuable assistance in the treatment; while the personal hygiene (especially clothing the child in flannel) is of great importance. Hot sand-bags placed in bed on each side of the affected limbs are useful at night.

We have directed attention to this treatment because it is based upon sound principles, and it has been subjected to the test of experience by an able observer, who assures us that it deserves a trial by the profession.

LEADING ARTICLE.

BATHS IN SKIN-DISEASES.

IT is a singular fact that, during all the centuries in which mankind has been giving and taking baths, no one has solved the problem as to the penetration of water through the skin. The balneological treatises of ancient, mediæval, and modern times, so far as we have examined them, have contained assertions *pro* and *contra*, no doubt; but it is only very recently that scientific investigations have been undertaken with the view of ascertaining with certainty how far the skin is permeable by water and by substances in watery solution. The point is one on which argument is easy, but demonstration difficult. Some years ago the books used to give the case of shipwrecked sailors who are able, it was said, to assuage the pangs of thirst by keeping their clothing constantly wet with sea-water, the inference being that some water must be absorbed through the skin. Scientific investigation, however, having proved that under ordinary circumstances a great loss of water is constantly taking place through evaporation from the skin, it is evident that the arrest of such evaporation would alone account for the limited relief gained by saturating the clothing with sea-water. In like manner the advocates of the various mineral springs of Europe have described minutely the advantages gained in one disease by bathing in one spring, while a neighboring one of almost precisely the same chemical composition and thermal qualities is said to exercise quite a different effect and to be useful in an entirely different class of diseases. To read the books written in description and praise of the mineral springs of the world, a long and dreary list, we might imagine that for every possible ailment some specific spring gushes from the earth in plenitude of healing power. And yet, eliminate the conscious and interested false statements, allow for the almost universal tendency to quackery and the belief in "nature's own remedies" and "mysterious virtues," take into account the influence of salubrious surroundings, regulated diet and regimen, and the concomitant employment of internal remedies, and, finally, consider how far the virtues of the waters are in many cases due to their thermic qualities, the regulated action of heat and moisture upon the body, and we can judge how little room is left for the specific effect of any substances which may be held in solution, even if it were possible that these could force an entrance through the skin and be taken up by the system.

The action and effect of water and its vapor, or of substances in watery solution, upon the system at large, and especially upon the skin, has only been carefully studied of late years. German and French physiologists have examined into the influence of various baths on the nervous and vascular systems, and also as regards the absorption of medicinal substances through the skin, until at present we are in the possession of sufficiently accurate data to form a practical estimate of baths as medicinal agents.

The effects produced by baths upon the skin, which alone will be the subject of inquiry in the present article, are of several kinds. In the first place, the temperature of the bath, without regard to its contents, has a certain effect. Thus, lukewarm and moderately hot baths diminish irritability of the peripheral ends of the cutaneous nerves, and for this reason are peculiarly valuable in cases where general pruritus constitutes a prominent symptom

or perchance essentially the disease itself. General pruritus of an idiopathic character is nearly always relieved by warm baths, and, with this in view, the careful practitioner will not neglect the employment of so valuable an adjuvant to the treatment by drugs. One practical drawback to the use of baths in some forms of pruritic skin-diseases lies in the fact that water is irritant to the broken skin, and thus in eczema the excellent thermic effect is neutralized by the chemical action of the water. This may be avoided by medicating the water in two ways,—by the addition of some demulcent, as starch or gelatin, or of some chemical agent, as borax or sodium carbonate. The exact influence of these agents in modifying the effect of water upon the raw and inflamed skin cannot be stated with precision. In the case of the sodium carbonate it is probably due to some principle connected with the osmosis of the fluids of the body: the sodium-solution being of a specific gravity approaching that of serum, transudation is prevented. Such, at least, is the theory which has been brought forward.

In the intense dermatitis of burns, and in skin-affections like pemphigus, where the epidermis has separated and the patient is, as it were, flayed, the continuous bath as devised by Hebra gives great comfort and relief. Hebra's bath consists of a convenient tub of large size, with a bedstead hanging by pulleys, etc., so that the patient can be raised and lowered as desired. In case of extensive burns, the water is introduced at a temperature of about 90° F., which is as hot as can at first be borne. After a few minutes the patient feels cold, and then the temperature of the water is raised to 104°–108° F., which gives great comfort. The patient remains in the bath day and night, eating, drinking, and sleeping in it, and being removed only for stool. Although not preventing the tendency to death in severe burns at the beginning, it gives much relief in the later suppurative stages.

The question of the absorption either of water or of substances dissolved in water through the uninjured skin is one of great interest. It is known that the skin is permeable in both directions for gaseous substances, and also that both sweat and sebum pass outward through the pores. Whether, however, water or watery solutions can be absorbed is as yet undecided, although the weight of scientific testimony is against such a view. The numerous experiments which have been made in this direction have for the most part been wanting in scientific accuracy, as has been pointed out recently by Leichtenstern, a writer of impartial and scientific spirit. Leichtenstern, as the result of a collation of the most accurate experiments of others and of his own investigations, concludes that imbibition of water and of salts dissolved in water may occur in the bath so far as the superficial layers of the epidermis are concerned; but this imbibition is not necessarily followed by absorption. Indeed, it is probable that the water imbibed during the bath is shortly afterwards lost by evaporation. In any case, the amount imbibed is so small as to elude estimation by weighing or otherwise. Various circumstances may favor cutaneous imbibition of watery solutions,—*e.g.*, warmth, long duration of the bath (up to several hours), and removal of the sebaceous greasy matter with which the skin is normally endued, either by previous washing with soap, or by repeated baths, or by the addition of detergent substances to the bath. According to Leichtenstern, the palms of the hands and the soles of the feet imbibe water most readily, on account of the absence of sebaceous glands from these parts. True absorption, in the proper sense of the term, of water and of salts or other non-volatile substances contained therein, has never been proved to take place in ordinary baths, although numerous experiments have been made to prove such a fact and assertions to the same effect are frequently met with in balneological literature. Another point of importance to remember is that the excretory ducts of the sweat and sebaceous glands are not so constituted as to be capable of absorbing water. To read the twaddle of the popular hygienists would lead to the belief that the "pores" of the skin are great open conduits, gaping and swallowing all that comes within their reach. So far from this, the gland-ducts afford all the resistance that minute canals lined with epithelium and blocked with oily matters (the sweat, it must be remembered, is mixed with sebum) can offer to the penetration of watery fluids. It is true, indeed, that by friction a minute quantity of water can be pressed into the gland-openings; but certainly the quan-

tity is too minute to exercise any appreciable physiological or therapeutic effect.

In the case of gaseous matters, however, the facts are somewhat different, for certain gaseous and volatile matters dissolved in water are, under appropriate circumstances, absorbed through the skin. Sulphurous acid and free iodine are thus taken into the system by means of baths. On the other hand, it is a curious fact that free carbonic acid is not absorbed, except in baths particularly rich in this gas, and even then only in small quantities.

The bearing of these facts on the therapeutic uses of baths is obvious, for if no absorption can take place through the skin except through chance fissures or the mucous membrane of the anus and genitalia, then the administration of many salts and other drugs by this method with a view to their constitutional effect must be an exceedingly clumsy and for the most part inefficacious proceeding. For while minute quantities of these substances may doubtless be absorbed, as a matter of fact, by whatever channel they enter the body, yet surely the number of drugs must be small and the necessities of the case peculiar which can lead to this method of administration.

Restricting, however, the use of baths in skin-diseases to those affections where they may be employed with real advantage, we have still a large number of cases where these can be employed with benefit to the patient. The use of warm-water baths in allaying irritation of the peripheral nerves has already been pointed out. A further use is found in those more or less generalized skin-diseases, as ichthyosis, where we have diminished secretion. Here the heat and moisture induce further action of the oil- and sweat-glands, and the macerating action of the water softens the dry, rough epidermis and prepares the way for ointments and other emollient applications.

The simple warm bath or the bath containing sodium carbonate is useful in cases of skin-disease when it is desirable to macerate and soften the crusts and scales before applying remedies. No marked curative effect, however, can be expected in diseases like psoriasis, for example.

In scabies and other animal or vegetable parasites of the skin, advantage is taken of the imbibition of watery solutions to destroy these parasites by appropriate medication, as by sulphuret-of-potassium baths. The water penetrates far enough at most points to destroy the itch-insect, and renders other medication, as by ointments, easier. In the mercurial vapor-bath we have an instance of the macerating and softening power of water in preparing the way for the entrance of volatilized mercury.

The known fact of the absorption of corrosive sublimate in watery solution in the baths given syphilitic infants is apparently in contradiction to the fact observed in physiological experiment, that watery solutions are not so absorbed. How the facts can be reconciled we cannot at present say. Both have been abundantly verified, however.

As regards the particular skin-affections in which the administration of baths may be employed to advantage, this is not the occasion to enter into the subject. We have only endeavored to give the general indications for their use, and to point out the value of this mode of treatment intelligently applied, and the necessity of understanding what may be accomplished by baths—what they can do and what they cannot do—in the cure of diseases of the skin.

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

NEW REMEDIES—Sparteine Sulphate.—The French medical world is at present in a state of excitement over the interesting subject of therapeutics, and we are able this month to give some details of the latest efforts made to introduce new remedies. One of the most recent is sulphate of sparteine, obtained from the broom-plant, *Spartium Scoparium*. Dr. Laborde, the chief of Professor Béclard's physiological laboratory, has made a number of experiments with this substance, and has discovered that it has a remarkable effect on the heart. In dogs to which were given doses of one centigramme, there was a considerable augmentation of the heart's action, and this result was not owing to any modification of the respiratory rhythm, because it continued after the animals were also given curare, so that he thought that the action of the drug was on the heart-muscle itself. Discovering that the sulphate of sparteine increases the energy of the heart's action without giving rise to toxic symptoms,

Dr. Laborde asked Professor Germain Sée to try it on his patients.

Dr. Sée thus reports on it: "Three characteristic and conclusive effects are the result of my observations. The first, which is the most important, is the quickening and renewed action of the heart and the pulse: in this it resembles digitalis or convallamarine, but its action as a cardiac tonic is very much more prompt than either of these, and more durable. The second effect is the regulation of the heart's rhythm that has been disturbed; and I believe that no other medicine can be compared with it for this purpose. The third result is the acceleration of the beat: this would be useful only in those cases of muscular atony with slowness of the beat: in this action it resembles belladonna. All these phenomena appear at the end of the first hour after the administration of the medicine, and the action maintains itself for three or four days after the drug has been discontinued. During this time the general strength is increased and respiration is easier: the urinary function alone does not seem to be influenced by the moderate doses I have used up to the present."

The sulphate of sparteine seems, then, to be applicable to some alteration in the heart: either when it has undergone an alteration in its tissue or has become incapable of compensating the obstacles to circulation. When the pulse is irregular, intermittent, and arhythmic, the sulphate of sparteine will rapidly re-establish the normal type. When the circulation has slowed up, the medicine seems to relieve this functional trouble, and at the same time it maintains and augments the newly-acquired force of the heart-muscle.

Terpene.—The principal objections to the employment of turpentine in medicine have been its insolubility in water, its odor, and its taste. The bihydrate of turpentine called terpene is exempt from these, and is now taking an important place in therapeutics. It has been used by Dr. Dujardin-Beaumetz and by Professor Germain Sée quite extensively. It is obtained by the hydration of turpenthène, which is a product of crude turpentine, at a temperature of one hundred and fifty-six degrees Centigrade. It is a white powder crystallized, and not a liquid, as often stated. It dissolves in two hundred parts of cold water, or in six or seven parts of alcohol. Its solutions have a bitter taste, but are not at all nauseating. Its characteristic chemical reactions are: nitric acid added to a solution gives an odor of hyacinth, and sulphuric acid gives a green precipitate; these reactions will show in the urine of patients taking the drug. There is still great dispute as to its action in health; but its effect on the patients who are ill is not contested. The administration of twenty to thirty centigrammes of terpene will augment the bronchial secretions and the expectoration. It is then an expectorant for use in subacute or chronic bronchitis. On raising the dose to eighty, or to one hundred, centigrammes (one gramme), terpene will provoke contractions of the vessels and also of the mucous membranes, arrest hemorrhage, and stop, or at least greatly lessen, bronchial secretion. It has checked very rapidly the hæmoptysis of commencing phthisis: so that in this dose it is a hæmostatic and a drier of bronchial secretion. (See on this subject an article by Dr. William Murrell on "Pure Terebene in the Treatment of Winter-Cough," in *British Medical Journal*, December 12, 1885.)

The following is Dr. Germain Sée's formula for its administration:

℞ Alcoholis (at 85), 250 grammes;
Aquæ, 30 grammes;
Terpene, 10 grammes. M.

Sig.—Three teaspoonfuls per day, to be given in lemon-syrup. It should be given with or directly after meals, to prevent any gastric trouble.

Hypnone.—We spoke of this substance in a late letter; but it has grown so rapidly in favor that it will be well to say something more on the subject. As before stated, it is a phenyl-methyl-acetone, to which Dr. Dujardin-Beaumetz has given the name of hypnone, owing to its decided hypnotic properties. It is now in constant use in all the hospitals, and the wholesale drug men are advertising it at ten cents a gramme. M. Dubois finds that patients submitted to its action before taking chloroform sleep much better. M. Laborde has made a series of experiments with it on animals, and finds that intravenous injections of the medicine rapidly produce sleep with anæsthesia and analgesia. Instilled into the eye, it produces local anæsthesia, but at the same time a most violent conjunctivitis.

The dose of hypnone is from six to eight drops, and the same, or even better, effects will be obtained from this dose as from two grammes of chloral or four grammes of paraldehyde. The hypnone needs alcohol at ninety degrees to dissolve it in rather a large quantity, so that M. A. Petit advises the following formula:

℞ Hypnone, 15 drops;
Alcoholis, 20 grammes;
Syrupi, 55 grammes;
Glycerini, 25 grammes. M.

Sig.—Each teaspoonful of this gives three drops of the hypnone. The remedy may also be given in capsules.

It is rather curious that for some time special attention has been directed to new hypnotics. We have now to speak of hopeine, extracted from hops, of which it is the supposed narcotic principle. We have also uréthane, which is a white substance, fusible at one hundred degrees Centigrade, easily crystallizable. All these, with chloral, paraldehyde, and still another, have close analo-

gies in their chemistry that are very curious, and will require a study of all the acetones, commencing with the ordinary acetone of acetic acid. The new remedy, hypnone, is obtained by dry distillation of a mixture of the acetate of calcium with the benzoate of calcium. The newest compound of this series is the benzophénone: this is obtained from the dry distillation of the benzoate of lime. It is in crystals of an amber color and an agreeable taste: it is now under experiment.

In regard to uréthane, it is now used very much in the German clinics by Von Jaksch, and by Sticker in Professor Riegel's clinic. It is a pure hypnotic, without being anodyne like chloroform or paregoric. It succeeds best in nervous insomnia, and calms the cough in phthisis. It is advised in one-gramme doses every half-hour or every hour, rather than in the massive doses, as given by some, of two to four grammes at once. Like the others of this series, it is well supported by patients, and the sleep produced resembles the normal physiological sleep. Certainly all this variety must afford a great relief to the tired morphia-eater.

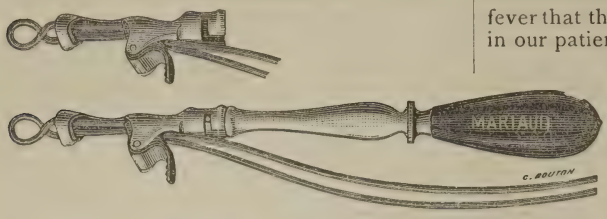
Dr. Desnos has just been studying some of our American plants, in particular the cholagogues and purgatives, such as baptisine, sanguinarine, juglandine, and phytolaccine, upon the human organism. He reports that "they are, all four, brown powders, having a salt taste, with an after-taste of bitterness. They are very hygrometric. I administered them in doses of five to ten centigrammes, under the form of plain pills. The baptisine is a resinous matter obtained by precipitation by water of the alcoholic tincture of Baptisia tinctoria. The sanguinarine is also a resin obtained from the Sanguinaria Canadensis. The Juglans cinerea of North America furnishes the juglandine, which is taken from the inner bark of the tree. The Phytolacca decandra, a beautiful plant of the United States, gives the phytolaccine. I tried it on seventeen patients in doses of ten to twenty centigrammes, and it seems to be the best of them all, provoking abundant stools containing a certain quantity of bile: in high doses it caused vomiting and depression. Baptisine, given in fourteen cases, was found to be a fair purgative, causing some colic; the juglandine about the same in the same doses, except that it seemed to cause irritation of the intestine. The sanguinarine, even in sixty-centigramme doses, gave only negative results. Phytolaccine is a reliable purgative: sure in its effects, without any inconveniences, it is an agent that should enrich the therapeutics of constipation."

Professor Vulpian has just made a report to the Académie de Médecine on the treatment of rheumatism by the salicylates. He stated that it is known that salicylate of sodium is efficacious in acute articular rheumatism and in acute attacks of articular gout, but its influence, however, is of not the slightest use in blennorrhagic rheumatism, and it is feeble in chronic and subacute forms of rheumatism. The salicylate of lithium seems to be quite as efficacious as the sodium in the first forms. In cases of patients treated by the salicylate of sodium, it often happens that after a rapid amelioration the joints remain tense and the use of the joints is still more or less constrained and painful. Now, even in doses high enough to be toxic, no further effect will be produced by the salicylate of sodium; and it is here that the salicylate of lithium will come in, and in a few days the last traces of the rheumatism will disappear.

The lithium salt seems to be quite as active in the treatment of those forms of acute rheumatism where the fibrous tissues are attacked, and it is more active than the sodium salicylate in the subacute forms of articular rheumatism that are progressive, and indeed even in many cases where salicylate of sodium has been faithfully tried. He had seen it fail, and yet, in a treatment of fifteen days, the use of salicylate of lithium led to complete success. In chronic articular rheumatism, when the joints may be more or less deformed and swollen, even half in a state of anchylosis, there will often be a marked improvement after the use of salicylate of lithium. In two cases of women at the hospital, they recovered the lost sleep and were able to move the limbs.

As in other medicines, there is a dose under which but little good will be obtained. For salicylate of lithium it is four grammes a day. Sometimes it will be necessary to give from four and a half to five grammes. When the improvement ceases, it will be sufficient to increase the dose fifty centigrammes. Intolerance will mostly come on at doses of five grammes to five and a half. He had seen some rheumatics resist a dose of six to seven grammes of salicylate of sodium that afterwards yielded to a dose of four grammes of salicylate of lithium. He therefore recommended the use of this preparation.

At a meeting of the Société de Médecine de Strasbourg, on the 3d instant, M. Koeberlé made a communication on an important simplification in the operation of hysterotomy by the use of an elastic ligator that Professor S. Pozzi, of the Paris Faculty, presented to the French Congress of Surgeons last summer. Dr. Pozzi's instrument is explained by the wood-cut on the next page. It is very simple, consisting of two pieces, which can be taken apart. The elastic cord is passed through, and, the button pressed, it is held in place. A simple turn of the instrument makes the cord cross, when it may be tied at leisure. Dr. Pozzi, in his interesting pamphlet on the subject of the "Technique of Elastic Ligatures," says that he prefers elastic cords, and not tubes. He uses round ones five millimetres in diameter. He regards the black as the



best kind. Dr. Koeberlé said, in regard to this method,—

"By the application of the elastic ligator of Dr. Pozzi, it is now possible to make but two ligatures (lateral) on each side: one in silk, placed outside the ovary across the large ligament, and the other wire, taking in the rest of the tissues up to the median line of the os uteri and the vagina. The wire ligature is placed after having first put the elastic one in. It is passed to each side of the fimbriated extremity of the broad ligament that has served for the attachment of the silk ligature. It can be transformed into a lost ligature after having excised the ovary on each side. The use of this elastic ligature with M. Pozzi's instrument, with a strong elastic cord, renders this operation so little serious, permitting any surgeon to make it, that now it is one of the regular operations of surgery."

M. Koeberlé did two hysterotomies with complete success. One of the tumors weighed eight kilogrammes (about eighteen pounds). In some sixty cases that were operated by M. Koeberlé, cure was the rule.

Professor Guyon, at the Necker Hospital, had an interesting case of vesical tuberculosis. He said, "I am about to perform the supra-pubic operation for a patient who is not one of the regular cases for that operation, as he has no stone in the bladder, but has tubercles there. The interest in this case is not only in the nature of it, but in the conditions under which we are obliged to interfere. The principal one is excessive pain, from which the patient has suffered for a long time without obtaining the slightest relief from any therapeutical means.

"This operation must be looked at from two points of view. First, does the nature of the lesion under which he is suffering permit us to make the operation or not? and, having resolved to do so, will it be of use to the patient? As to the first point, we must ask ourselves if the traumatism will not have the effect of doing more harm than good. This question was raised by Professor Verneuil, and it is of great importance, as operations on these patients have suddenly aggravated their general condition; but in this case it is not likely such a result will follow.

"The tuberculosis here is local, and it has been demonstrated that instrumental interference in such cases will often produce an amelioration and sometimes a cure. Experience has also shown that it is when there is fever that there is danger of after-trouble; but in our patient no fever is present. As to the question whether we are justified in operating, owing to the painful condition of the bladder, here we must state that this is a delicate question that is far from being settled. This is owing in great part to the number of cases in which the diagnosis of tuberculosis has been wrongly made, and where often a painful cystitis has been mistaken for it. The first thing to do, then, is to be sure of the diagnosis. Let us take the history of the case. A young man, 24 years of age, comes before us without any pathological antecedents and without any blennorrhagic troubles. That will exclude any chance of a local infection by contagion. The commencement of this was noticed when he was in the army, and found that he had frequent need to urinate (without pain, however). On being sent to the hospital, sounds were used, but without any benefit; on the contrary, it increased the difficulty, and he had pain, which was intense at the end of the act of micturition. He was obliged to rise fifteen to twenty times at night, and the pain was such that it felt like a knife cutting the urethra all along its course."

After coming under the professor's charge he was able with morphine to calm the pain for a time. When the clinical march of this trouble is taken into consideration, notwithstanding the fact that physical examination did not reveal anything, he did not hesitate to call it tuberculosis of the bladder, because the symptoms came without any previous exciting cause (such as blennorrhagia), without any constriction, without traumatism, without any foreign body in the bladder, and without any of the usual causes of cystitis, including hæmaturia. Examination of the urine took away all doubt, as a number of the bacilli of tuberculosis were found.

As to the danger in this operation, this is the third time that he had performed it in such cases. In the other two cases the cicatrization of the wound was only too rapid: it was followed by complete cessation of pain. The operation, then, offering no danger, is it useful? This is without doubt. After the bladder is open, he said, the manner of proceeding would depend upon circumstances. If the growth be not too extensive, he would endeavor to remove it as completely as possible. He would utilize Petersen's balloon, with vesical dilatation. In regard to this, the dilatation of the bladder must be made with great care, and the best test of this may be found in the behavior of the bladder: when the patient is sleeping profoundly under chloroform, the bladder must not resist the injection of small quantities of liquid. If it does, —if, notwithstanding the anæsthesia, it continues to resist,—then it must not be distended.

M. Pasteur is going on at a great rate with

his inoculations. The government officials have visited his place: they saw some forty persons operated upon, and after the visit they decided to present a bill to Parliament to furnish him with a proper building in which he can continue his experiments, so that before long there will be a hydrophobia hospital here. Patients are flocking in from all over the world, America giving her share. It may be stated, however, that M. Pasteur is only too glad to see others try his simple system, and, since the rabbit-marrows are sold to proper parties applying, we do not see why your surgeons do not try the system for themselves, instead of sending patients over here.

THOMAS LINN, M.D.

PARIS, FRANCE, December 18, 1885.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA ACADEMY OF SURGERY.

(Continued from page 291.)

A STATED meeting of the Philadelphia Academy of Surgery was held December 7, 1885, the President, Dr. D. Hayes Agnew, in the chair.

DIPHTHERITIC CASTS FROM THE URETER.

Dr. Thomas G. Morton also related the following history of a case. On the 5th of November last, a lad, 14 years of age, was admitted into the Pennsylvania Hospital with violent cystitis and symptoms of stone. At the age of four years he had been operated on for stone in Ireland, and a good-sized calculus removed. Since then, and until six months ago, he had remained well. He then experienced pain in the bladder, urethra, and at the end of the penis, and had frequent stoppage of urine, which was due to plugs of dense matter which lodged in the urethra or meatus, and he said that he experienced great difficulty in forcing them out, after which the flow of urine would be free.

On admission, he was very pale, feeble, and in constant suffering. The bladder was examined, and no foreign body was detected. He was given anodynes, placed upon the milk diet, and the bladder was washed out daily. The urine contained albumen, pus, and the fragments of membrane, which were constantly discharged or extracted from the urethra, and appeared to be tubes from which a longitudinal strip had been removed. A week after the first examination, the symptoms continuing, he was again etherized and the bladder examined, and, although no stone was detected, I decided to perform cystotomy. At the time of operation one of the plugs of membrane blocked up the meatus, and required some effort with a forceps to remove it. In the bladder I found about two tablespoonfuls of false membrane in a mass made up in part of incomplete tubes; and as this was adjacent to the right ureter, and as the patient had had some symptoms of discomfort in this and the kidney region, it seemed possible that these tubes were thrown off from the ureter on this side.

In the meshes of the mass of membrane removed there was a considerable deposit of calcareous matter, and numerous fragments of stone weighing probably four or six grains. The mass had likely been accumulating for a long time.

The bladder-wound has been kept open by a large silver tube, and injections used daily. The presence of the membrane has almost ceased, and little or no suffering is experienced. There were no symptoms, it appears, such as seen in diphtheria at any time in the course of his illness, although there was a hectic condition when the patient was first received.

DISCUSSION.

Dr. John B. Roberts: I have never seen a case in which tubes of this kind were passed. At a meeting of the Clinical Society, two or three weeks ago, a series of blood-casts from the ureter were shown. These of course were solid. They looked so much like worms that the woman at first supposed that she was passing worms. They had the appearance of earth-worms. They were examined, I believe, by Dr. Leidy, who pronounced them to be clots.

Dr. J. H. Brinton: The report of Dr. Morton's case has suggested one which I now have under treatment, and about which I am somewhat puzzled. Six or seven weeks ago a man of 36 presented himself to me with partial anchylosis of the left hip-joint: the thigh was turned inward, and flexion was arrested at an angle of one hundred and thirty-five degrees. He told me that he passed no urine through the urethra, but that all escaped through a series of openings extending from the groin far back into the perineum. There were nine of these openings, and more water passed through the posterior than through the anterior ones, although some time since a large quantity of water passed through the anterior channels. He had suffered much pain, and was greatly emaciated.

On examining the urethra I found marked narrowing at and behind the membranous portion; at the same time the presence of some hard foreign substance could be detected between this portion of the urethra and the neck of the bladder. A small lithotrite was then introduced, when I succeeded in extracting three or four portions of bone. These varied from three-fourths of an inch in length to the size of a grain of coffee. He then remembered that he had passed a piece of bone from one of these external openings. From the history furnished by the patient, it was evident that he had suffered from scrofulous

disease of the bones of the pelvis, and especially of the acetabulum, when a child. This condition had continued for twenty-seven years, the patient being better or worse at intervals. During the past two or three years the flow of urine through the urethra has been much interfered with, and during the last few months all of his urine has passed by the fistulous channels.

In view of the exfoliations and of the probable diseased conditions in front of the bladder, I determined to open up the parts by the median cut,—in this instance not strictly a median operation, since on account of the displacement of the parts due to the anchylosis I was obliged to cut in the line of a curved raphé. I then opened the membranous urethra, and, passing upward, reached a cavity containing pus and urine, and directed towards the left or diseased side.

This cavity was most probably the bladder distorted to the left side, bound down, and having suffered some loss of substance, or else it was a cavity or cyst formed in front of and communicating with the bladder. I had at first hoped that by treating the case as one of the median section for cystitis I could accomplish a cure; but the condition of the parts, as developed at the operation, seemed to me to obscure the prognosis.

Since the operation the patient has in some respects done well: his pain has disappeared, he has gained flesh, and generally he is in every way better. Locally, however, his progress has not been all that I could wish. The treatment has consisted in keeping the urethra well dilated by an india-rubber catheter,—at times kept in continuously, and at other times introduced at short intervals. The median cut has also been kept open, although a rapid tendency to heal is present. The patient can now readily retain his water for two hours. After that time it will escape; and although some urine passes by the median cut, yet it undoubtedly manifests a preference to escape by three or four of the posterior fistulous openings. None now passes by the anterior openings, those near the groin and on the front part of the thigh. When the catheter is introduced into the bladder a small quantity of purulent matter, say a drachm, sometimes escapes before and usually follows the flow of urine.

The President: It is probable that the bladder is tied down to the side of the pelvis, so that when it is empty that portion forms a little sac or diverticulum. If such is the case, it will be a difficult matter to cure it. In order that the bladder shall empty itself, it is necessary that it shall contract in all directions.

Dr. J. William White: The indication in such a case seems to be to keep a full-sized catheter in the urethra or the perineal opening all the time. The genu-pectoral position would also probably help to drain the bladder.

Dr. Nancrede: How would it do to make a supra-pubic incision for exploring the bladder?

Dr. J. H. Brinton: I have thought of that for a future operation.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Meeting of December 28, 1885.

The President, Daniel Lewis, M.D., in the chair.

PROLONGED LOCAL ANÆSTHETIZATION BY INCARCERATION OF THE ANÆSTHETIC FLUID IN THE FIELD OF OPERATION.

Dr. J. Leonard Corning read a paper on this subject. By experiment he had learned that, by shutting off the circulation from the part to be anæsthetized by hydrochlorate of cocaine, insensibility produced by the drug could be indefinitely prolonged. The reasons for this were not hard to conceive. We were thus enabled to reduce the constitutional symptoms to a minimum. Here were advantages not to be overestimated; for if, as in the ordinary method without incarceration of the anæsthetic, we inject a sufficiently-concentrated form to influence the general nervous system, there would be liability of establishing a change in the nerve-filaments of the brain and cord. In speaking of the very low percentage of cocaine which would produce anæsthesia when incarcerated, Dr. Corning had found a one-, a one-half-, a one-third-, and even a one-fifth-per-cent. solution of the cocaine to produce insensibility. A one-fifth-per-cent. solution, however, is too weak for practical use. For ordinary purposes, a solution of one-half to one per cent. is most desirable.

In order to avoid injection of the solution into the lumen of large veins, Dr. Corning applied a moderately strong rubber band around the limb, obstructing the return-circulation, and, having thus rendered the veins prominent, he mapped out their course with a soft blue pencil. This was the more important inasmuch as, after applying Esmarch's bandage and rendering the limb bloodless, preparatory for the injection, the course of the veins could not be seen. Having mapped out the veins, he rendered the part bloodless nearly up to the point of operation by Esmarch's bandage, then made the injection just below the margin of the tourniquet, which was tightened shortly after making the injection. At first, two to five minims of the fluid were injected just under the epidermis, and, having rendered the superficial parts insensitive, the needle could be made to penetrate more deeply without causing the patient more than trifling pain. The greater the extent of the operation, the weaker should

the solution be, if we wished to avoid producing constitutional symptoms. It was necessary to make the injections as rapidly as possible, in order to avoid deportation of the anæsthetic by the blood-stream before applying the tourniquet. The tourniquet should be applied just above the anæsthetic zone. The extent of the zone was measured by the æsthesiometric probe.

In cases of operations upon the face and parts of the body where the tourniquet could not be employed, Dr. Corning made use of hæmostatic rings. These made pressure upon the integument surrounding the field which it was desired to operate upon, and while they did not so completely cut off the circulation as did the tourniquet, still they incarcerated the anæsthetic sufficiently to permit of a severe and protracted operation without danger of constitutional symptoms from the amount of cocaine used.

Dr. Daniel Lewis, Dr. M. J. Roberts, and many others could now testify to the practical working of this method.

The PRESIDENT said the case referred to by Dr. Corning, in which he employed this method, was one of recurring epithelioma of the left shoulder. The incision made was three and a half inches long, and the skin was unusually thick; yet the patient experienced practically no pain during the operation, which lasted about forty minutes. The hæmostatic ring was used for incarcerating the anæsthetic.

Dr. M. J. ROBERTS had employed this method with satisfaction in exsection of the elbow-joint, of the hip-joint, in scraping out large abscess-cavities, etc. He thought the method marked a signal advance in anæsthesia.

THE TREATMENT OF PELVIC ABSCESS IN WOMEN BY INCISION AND DRAINAGE.

Dr. PAUL F. MUNDÉ read a paper on this subject, in which he said that in the majority of cases recovery took place after exudation following pelvic cellulitis and pelvic peritonitis, but in some instances a long period of time elapsed before complete absorption of the exudate occurred. In some cases the exudate broke down and formed an abscess. This was most likely to take place when the exudation was large and formed rapidly, and when the recuperative powers of the patient were below par. The majority of cases of pelvic abscess followed cellulitis, the minority followed peritonitis. In the cases of abscess referred to in this paper and following pelvic peritonitis, although the abscess really formed within the peritoneal cavity, it was practically shut off from that cavity, becoming, as it were, extra-peritoneal by the pathological changes which took place. Fortunately, the necessity for making a differential diagnosis between the two classes of cases, those developing in connection with pelvic cellulitis and those in connection with pelvic peritonitis, did not often arise.

From among four hundred cases of pelvic cellulitis and peritonitis of which he had records, only forty-eight terminated in pelvic abscess. Dr. Mundé thought that this percentage was larger than usual, because many of the cases, twenty-one, were seen in consultation. Twenty-three of the cases opened spontaneously; eight were treated by free incision and drainage (six through the abdominal wall and two through the vagina); in three cases there was instituted abdomino-vaginal drainage. All of the cases operated upon recovered. Dr. Mundé had seen only one case in which he thought the patient must necessarily die.

When he suspected suppuration in a case of pelvic exudation, he first proceeded to verify his suspicion by the introduction of the aspirator-needle. If only a small amount of pus was supposed to be present, he attempted to remove it by aspiration through the point of selection, usually in the vagina. If a number of small abscesses were suspected of being present, the aspiration was repeated until all were evacuated. Some years ago he reported eight cases treated in this manner, and since then he had so treated eight more, and in none had he had occasion to regret the procedure. In one, however, the case turned out to be one of dermoid cyst, and, had an incision been made in the first place, the true nature of the condition would have been earlier recognized. But it was not advisable to treat a case by simple aspiration if the abscess-cavity contained as much as three ounces of pus. Here the walls would not collapse and unite, but the cavity would refill with pus.

The treatment should be by free incision, in order to effect perfect drainage. Usually the spontaneous opening which formed in the rectum was too high up to be reached and more freely divided, and Dr. Mundé doubted whether the rectal opening should be enlarged anyway, for the contact of fæces would probably produce additional inflammation. If not treated, the patient might go on for years, with occasional discharges of pus through the opening in the rectum. But, if the spontaneous opening formed in the bladder, the drainage would be better than if it occurred in the rectum, and the wound would usually heal in a comparatively short time. A spontaneous opening through the vaginal wall, if small, might become obstructed by a clot or a fold of the mucous membrane, and prevent free drainage and union. The opening should be enlarged, the abscess-walls scraped, and, if necessary, a drainage-tube inserted. If the drainage-tube became irritating or did not effect complete drainage, the cavity should be injected once or twice a day with an antiseptic solution. Insufflation of iodoform was sometimes employed.

Dr. Mundé referred briefly to some of the unusual forms of pelvic abscess. The pus might find its way down to the perineum, or the point of fluctuation might be found at the crest of the ilium on one side. The abscess-cavity might be very large, containing more than a pint of pus, and there might be sinuses communicating with other collections of pus in the pelvic cavity. If fluctuation appeared near the crest of the ilium, the aspirator should be introduced, and, if pus were found, the grooved director should be introduced, and an incision made with a blunt-pointed bistoury. Then all sinuses should be explored. If the epigastric artery were divided, it should be ligated. As a rule, the freer the incision, the more quickly would the abscess heal. If pus had burrowed deeply into the pelvic cavity, an abdominal incision alone would not answer; it would be necessary to make a counter-opening through the vagina and establish thorough drainage. Daily antiseptic injections should then be practised. If the abscess were high up and adhesions had formed to the abdominal wall, the sac of the abscess being practically extra-peritoneal, drainage should be established through an incision, care being taken not to injure the peritoneum.

Dr. Mundé had embodied in his paper the histories of ten cases which he did not read.

Dr. W. M. Polk thought the paper a very good exposition of recognized methods for treating pelvic abscesses in women; he had, however, hoped to hear something new, especially with regard to the management of certain difficult cases which we come across in practice, and in which ordinary methods fail to obliterate the abscesses. Dr. Polk gave the physical signs and the treatment adopted in a case of deep pelvic abscess having no connection with the vagina, in which he made an abdominal incision and reached the abscess in that way. Although Dr. Mundé seemed disposed to criticise the procedure, Dr. Polk said he felt quite sure that even Dr. Mundé would not have discovered or reached the abscess through the vagina: other surgeons than himself had failed to do so. The mortality from pelvic abscess he thought was greater than was stated in the paper. There were some cases, he believed, in which numerous cavities and sinuses existed in the pelvic cavity, which rendered it impossible to stop the suppurative process which was destroying the life of the patient, in which he thought we would be justified in opening the abdomen, lifting the intestines out of the pelvic cavity, and incising the abscesses and sinuses. Dr. Polk pointed out the danger of wounding the uterine artery in making openings through the vaginal wall.

Dr. W. T. Lusk had also been led to suppose that the mortality from pelvic abscess was greater than had been represented this evening, and the need of a practical paper on the subject was evident. He had seen some cases in which the pelvis was almost riddled with abscesses, yet a cure was effected by thorough drainage. He was once very apprehensive on seeing a physician make extensive exploration through an opening in the vaginal wall for the purpose of breaking up the cavities and establishing drainage; but the patient recovered. The danger of mistaking pelvic abscess for ovarian cyst and other conditions was sometimes considerable.

Dr. W. Gill Wylie thought most cases of pelvic abscess resulted, not from pelvic cellulitis, but from pelvic peritonitis arising from the Fallopian tube, its ligament, and the ovary. The tube became rolled backward and obstructed, and an abscess was liable to form which might either burrow downward and have for its walls the cellular tissue in the pelvic cavity, or extend upward and form an abscess in the peritoneum and cause danger of death from peritonitis. In exploring an opening in the vagina made by a pelvic abscess, he would not cut, but dilate, thus avoiding injury to the artery.

The paper was further discussed by Drs. Irwin, Putnam Jacobi, Fruitnight, and the author.

Dr. Putnam Jacobi had followed Dr. Mundé's instructions, laid down in a former paper, to puncture with the hypodermic needle in a case of supposed pelvic abscess following an acute cellulitis, but she feared the punctures helped to bring on the formation of pus. The question was, how early after an acute attack of pelvic cellulitis should aspiration be done in order to determine the presence of small collections of pus.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held December 23, 1885, the President, John A. Wyeth, M.D., in the chair.

CARCINOMA OF THE STOMACH.

Dr. R. Van Santvoord reported that the specimens presented at the last meeting as supposed specimens of multiple myoma involving the stomach, bladder, and rectum were found, on microscopical examination, to be carcinoma.

MULTIPLE URETHRAL STRICTURE; PERINEAL ABSCESS.

Dr. Wackerhagen presented the genito-urinary apparatus removed from the body of a man 45 years of age, who, twenty years ago, had suffered from gonorrhœa. No noticeable sequelæ followed until last spring, when the patient noticed a swelling in the perineum, and afterwards had a perineal abscess, frequent urination, and, finally, dribbling of urine through a perineal fistula. When Dr. Wackerhagen saw the patient in

consultation last November, three urethral strictures were discovered, the meatus urinarius was contracted, and there was phimosis. Circumcision and internal urethrotomy were performed, and nine days afterwards external urethrotomy. The patient died eight days after the second operation. There was no elevation of temperature until within a few days before death, and the highest temperature reached was 102° F.; there had been no chill. The autopsy revealed a laceration of the mucous membrane of the urethra, and between this and the prostate was a fistula leading to a perineal abscess with principal dimensions of two and a half by two inches. The cavity of the bladder was about equal to that of the perineal abscess. There was slight dilatation of the ureters, and in the left kidney were abscess-cavities.

The PRESIDENT said that he had a similar case under care, the only difference in the history being that his patient had had chills.

SYMPTOMS SIMULATING TUBERCULOSIS.

Dr. L. EMMET HOLT presented two sets of specimens, removed from children, which were chiefly interesting from a point of contrast. In the one case the child had distinct symptoms of tubercular meningitis, but the autopsy revealed no tubercles whatever; there was slight cirrhosis of the liver. In the other case the child was apparently in excellent health until within three days of death, but at the autopsy tubercles were found in the lungs, liver, spleen, and kidneys. During the presence of the cerebral symptoms in the first case four doses of quinine were given, and there was active dentition, which might partly account for the symptoms.

Dr. AMIDON said it was his firm belief that some cases of tubercular meningitis recovered. He referred to one which came under his observation, in which recovery took place during the use of heroic doses of iodide of potassium. There was diplopia, frontal headache, facial paralysis on the right side, excessive photophobia, and maniacal disturbance at night. The patient was an adult, and was in a condition of advanced phthisis, and, although her condition was not such as to justify heroic treatment, she was treated by the administration of what amounted to about an ounce of the iodide of potassium in twenty-four hours. She recovered entirely from the cerebral symptoms, and at the autopsy (the patient dying some time afterwards) not a trace of meningitis could be found. He had always regarded it as a case of tubercular meningitis cured. The patient had no history of syphilis. She had well-marked pulmonary tuberculosis.

Dr. VAN SANTVOORD remarked that in the case of children marked cerebral symptoms were very frequently coincident with other disturbances, and he had been so frequently disappointed with reference to diagnosis and post-mortem changes that he had refrained from making a diagnosis until he saw the lesion in the dead-house.

Dr. PUTNAM JACOBI said that the proximate cause of symptoms in tubercular meningitis was hyperæmia of the meninges and softening of the gray matter around the tubercles and immediately under the meninges. Thus we might suspect tubercular meningitis and it might be simulated by any cause which would produce hyperæmia of the meninges.

Dr. VAN SANTVOORD had been struck with the extreme latency of the course of tubercular meningitis in some cases. He recalled one particularly, in which the process was of weeks' and even months' duration, and gave rise to marked cerebral symptoms only a few days before death.

Dr. J. C. PETERS said he had never seen a fatal case of tubercular meningitis unless there was evidence of tubercles in other organs, and he also thought it was exceedingly rare for recovery to take place if there was tuberculosis elsewhere.

Dr. AMIDON remarked that a very trifling lesion in the brain could kill a patient, and that he had been obliged sometimes to hunt for lesions in order to find that which was the cause of death.

Dr. HOLT said it had always seemed to him not fair to assume that because a patient recovers it is not a case of tubercular meningitis, for we see recoveries from tuberculosis elsewhere, as in tubercular disease of the bones and pulmonary tuberculosis, and therefore we should never hesitate to attack one of these cases with the hope of curing it.

Dr. VAN SANTVOORD asked if, in cases of recovery from pulmonary tuberculosis and tubercular disease of bone, Dr. Holt would not expect to find some lesion at the autopsy.

Dr. HOLT said he did not wish to imply that there was no lesion, but that some trace of the disease would be found.

The PRESIDENT said he was acquainted with a case in which the patient, a man 43 years of age, was under Dr. Janeway's care, who considers that he is now suffering from tubercular meningitis and has been for a considerable length of time.

Dr. PRUDDEN thought it was dangerous to draw an analogy with reference to tubercular meningitis from the healing of lesions in the lungs, because the only way in which the pulmonary cure is effected is by the process going on to fibroid degeneration.

Dr. HOLT would like to direct attention to the occurrence of simple dysentery in young children. This was the third autopsy which he had made within two weeks in which there was simple dysentery disconnected with any other lesion in the intestine. Goodhart states that simple dysentery is extremely rare apart from lesion of the small intestines. In the two cases mentioned the dysentery was largely follicular.

Dr. VAN SANTVOORD had seen considerable dysentery in children, but it had usually been follicular; indeed, he did not recall a case in which he had seen croupous dysentery.

NEW YORK ACADEMY OF MEDICINE.

THE Annual Meeting was held January 6, 1886, A. JACOBI, M.D., President, in the chair.

The President read the names of a number of gentlemen who had declined nominations for office. At the close of the balloting, the following were declared duly elected:

Vice-President, Dr. Henry D. Noyes; Corresponding Secretary, Dr. Wesley M. Carpenter; Treasurer, Dr. W. F. Cushman; Trustee, Dr. George A. Peters; Committee on Admission, Dr. J. H. Emerson; Recording Secretary, Dr. A. M. Jacobus; Committee on Library, Dr. W. H. Katzenbach and Dr. Laurence Johnson; Delegates to the State Medical Society, Drs. W. R. Birdsall, R. W. Amidon, A. S. Hunter, W. E. Bullard, and Gorham Bacon.

CONTAGIOUS DISEASES IN ASYLUMS AND RESIDENTIAL INSTITUTIONS.

Dr. R. H. DERBY, of the committee appointed to make investigation with regard to contagious diseases, particularly eye-diseases, in asylums and residential institutions, said the reports of those physicians appointed to visit the institutions represented them in a less favorable condition than they were in June last. In three asylums in the city, containing collectively about one thousand inmates, there were near three hundred cases of contagious eye-disease. Overcrowding, bad drainage, want of place for quarantine, were noticeable. The committee recommended that the influence of the Academy be exerted upon the Legislature towards the passage of a bill which had been kindly drawn up by Mr. Gerry, of the Society for the Prevention of Cruelty, and of which the following are the essential features:

That every incorporated institution in this city receiving children shall have attached to it a physician whose duty shall be to examine every child before admission, and give a certificate in writing that the child is a safe and proper subject to be accepted into the institution, being without contagious or infectious disease, especially of the eyes. Any inmate with contagious or infectious disease shall be placed in quarantine for ten days, to be released then only on recommendation of the physician. It shall be the duty of the physician at least once a month to inspect thoroughly the entire institution and report to the Board of Health. The beds shall be separated by a passage not less than two feet horizontally, and free ventilation secured. The minimum amount of air for each inmate in the dormitory shall be six hundred cubic feet. Any official refusing to comply with this act shall be guilty of a misdemeanor. This act to take effect on the first day of July, 1886.

On motion, the recommendation was adopted and the committee continued.

The annual reports were then received. According to the Treasurer's report, there was a balance in the treasury of eight hundred and eighty dollars, and no debt. The entire number of volumes in the library, including pamphlets and medical journals, was twenty-seven thousand.

CHANGES IN CONSTITUTION AND BY-LAWS.

The most important changes made related to the abolition of the Committee on Ethics; the Committee on Medical Education was also abolished.

On motion of Dr. AGNEW, the following was adopted as a part of the By-Laws:

"The Council shall, on a written statement signed by the complainant and duly forwarded through the Secretary, take cognizance of any complaint against a Fellow. The Council may, after investigation, dismiss the complaint or transmit its findings thereon for further action by the Academy."

REVIEWS AND BOOK NOTICES.

VON ZIEMSSEN'S HAND-BOOK OF GENERAL THERAPEUTICS. In Seven Volumes. Vol. I. Introduction by PROFESSOR H. VON ZIEMSSEN. On the Dietary of the Sick and Dietetic Methods of Treatment. On the Koumiss Cure. Vol. II. Antipyretic and Antiphlogistic Methods of Treatment. Epidermic, Endermic, and Hypodermic Administration of Medicines. Vol. III. Respiratory Therapeutics. New York, William Wood & Co., 1885.

This work has been written for the well-educated and scientific physician, who will find in its pages much that is valuable and suggestive with regard to the nature and rational treatment of morbid conditions. In accordance with the teachings of modern medicine, which awards a high place to dietetics in the treatment of disease,—reviving the principles of the famous school of Salernum,—a treatise upon Dietary of the Sick and Dietetic Methods of Treatment, by Professor J. Bauer, and a chapter on the koumiss cure by Dr. Stange, with a general introduction to the work by Professor H. Von Ziemssen, appropriately occupy the first volume of the series. The food-value of each article is first considered, in order that a dietary may be constructed for special cases. With regard to the food-value of alcoholic liquors, the opinion is expressed that "their favorable effect in many diseases is satisfac-

torily explained if we regard them solely as excitants and stimulants,—those especially which contain no appreciable constituents other than alcohol and water,—and estimate their nutritive properties as insignificant."

Liebermeister, Jürgensen, and Eulenberg contribute the essays which constitute the second volume, on Antipyretic Methods of Treatment, Antiphlogistic Methods of Treatment, and on Epidermic, Endermic, and Hypodermic Administration of Medicines, respectively. At the present day, when so much attention has been directed towards the treatment of fever and inflammation, and when especially the scientific status of venesection is under dispute, and when hypodermic and epidermic methods of administration are largely practised, their able and systematic treatment will be gladly welcomed. The translator, Mr. Matthew Hay, of Aberdeen University, has added a note upon some new antipyretics, and has made suggestions which considerably add to the value of the work.

Respiratory Therapeutics, by Professor M. J. Oertel, constitutes Volume III., which has been translated, with notes and a preface, by J. Burney Yeo, of London. In this not only the therapeutics of diseases of the air-passages are considered, but also the respiratory disorders accompanying organic disease of the organs of circulation. The *modus operandi* of the various methods of treatment is fully considered, as well as the drugs required in respiratory therapeutics.

The publication of these volumes indicates a highly-satisfactory condition of modern therapeutics, which is now more than ever approaching scientific exactness of application. The volumes are illustrated and well printed. As a work of reference, this Hand-Book promises, when complete, to comprise everything of value within its scope, and well deserves to be found in every medical library worthy of the name.

THE PRACTICE OF PHARMACY: A Treatise on the Modes of Making and Dispensing Officinal, Unofficinal, and Extemporaneous Preparations, and Descriptions of their Properties, Uses, and Doses. Intended as a Hand-Book for Pharmacists and Physicians, and a Text-Book for Students. By JOSEPH P. REMINGTON, Ph.G., etc. With nearly Five Hundred Illustrations. Philadelphia and London, J. B. Lippincott Company, 1885. 8vo, cloth, pp. 1080.

This work is encyclopædic in fulness, and within the limits of a single volume comprises a pharmaceutical reference-library. The various subjects are considered systematically and compendiously in sixty-eight chapters, the work being divided into six parts for convenience of study and to facilitate reference. The technics of pharmacy and the various methods of manipulation are considered quite fully in the first part; while in the second the student is made familiar with officinal pharmacy and pharmacopœial methods. Part three considers inorganic substances, and part four organic drugs; extemporaneous pharmacy is treated of in part five; while the concluding part contains a useful formulary of unofficinal preparations. The work is profusely illustrated, and the book is well printed and bound in admirable manner, as becomes a work of reference. This book will find a welcome place on the book-shelf of every physician, as well as of every pharmacist.

A GUIDE TO SANITARY HOUSE-INSPECTION; or, Hints and Helps regarding the Choice of a Healthful Home in City or Country. By WILLIAM PAUL GERHARD, C.E., Consulting Sanitary Engineer. New York, John Wiley & Sons, 1885. Cloth, 12mo, pp. 145.

The English language, rich in the possession of the word home, contains many qualifying expressions, such as a happy home, the home of refinement, comfort, even of luxury, but the idea is rapidly developing in the community that health must take precedence of all other considerations, and that in order to enjoy life a healthful home is the prime necessity. The cause to which the melancholy fact that so many dwelling-houses have serious defects of construction is to be attributed is ignorance,—ignorance, especially on the part of the householder, of the requirements for safe habitation, and ignorance as well as cupidity on the part of the plumber and "skin builder." The present volume is a sanitary tract for the householder and sanitary inspector. The necessity of such inspection is made evident by a perusal of this work, which is clearly written, and contains advice which, if intelligently followed, will be worth many times its cost.

NEW BOOKS.

CLINICAL THERAPEUTICS. Lectures in Practical Medicine, delivered in the Hospital at St.-Antoine, Paris, France. By Prof. DUJARDIN-BEAUMETZ. The Treatment of Nervous Diseases, of General Diseases, and of Fevers. Translated by E. P. HURD, M D Detroit, Michigan, George S. Davis, 1885. Cloth, 8vo, pp. 491.

TABLETS OF ANATOMY. By THOMAS COOKE, F R.C.S. Eng. Fourth Edition; or, Selection of Tablets believed to be most useful to Students generally. Longmans, Green & Co., London, 1885. For sale by J. B. Lippincott Company.

PRACTICAL NOTES ON THE TREATMENT OF SKIN-DISEASES. DISEASES OF THE PERSPIRATORY AND SEBACEOUS GLANDS. By GEORGE H. ROHÉ, M.D. Baltimore, 1885. 12mo, paper, pp. 62.

ELECTRICITY IN MEDICINE. Illustrated. By AMBROSE L. RANNEY, M.D. New York, D. Appleton & Co. Cloth, 12mo, pp. 147.

HOW WE TREAT WOUNDS TO-DAY. By ROBERT J. MORRIS, M.D. New York and London, G. P. Putnam's Sons, 1886. Cloth, 12mo, pp. 160.

PSYCHIATRY: A CLINICAL TREATISE ON DISEASES OF THE FORE-BRAIN, BASED UPON A STUDY OF ITS STRUCTURE, FUNCTIONS, AND NUTRITION. By THEODORE MEYNERT, M.D. Translated (by authority) by B. SACHS, M.D. Part I. The Anatomy, Physiology, and Chemistry of the Brain. Illustrated. G. P. Putnam's Sons, New York and London, 1885. Pp. 285.

BASIC AURAL DYSCRASIA AND VASCULAR DEAFNESS. A New System of Aural Therapeutics and Pathology. Also Notes on the Deafnesses. By ROBERT HOOPER, M.D. Ballière, Tindall & Cox, London, 1886.

CLINICAL NOTES ON UTERINE SURGERY. With Special Reference to the Sterile Condition. By J. MARION SIMS, A.B., M.D. Memorial Edition. Wm. Wood & Co., New York, 1886.

THE FIELD AND LIMITATION OF THE OPERATIVE SURGERY OF THE HUMAN BRAIN. By JOHN B. ROBERTS, M.D. P. Blakiston & Co., Philadelphia, 1885. 8vo, cloth. Pp. 80.

WOOD'S LIBRARY:

CLIMATOLOGY AND MINERAL WATERS OF THE UNITED STATES. By A. N. BELL, A.M., M.D. (October.)

DISEASES OF THE LUNGS. By PROFESSOR GERMAIN SÉE. (November.)

DISEASES OF THE BRAIN AND SPINAL CORD. By W. R. GOWERS, M.D., F.R.C.P. (December.) Wm. Wood & Co., New York, 1885.

WOOD'S POCKET MANUALS:

CUTANEOUS MEMORANDA. By HENRY G. PIFFARD, M.D.

VENEREAL MEMORANDA. A Manual for the Student and Practitioner. By A. MORROW, M.D.

MISCELLANY.

LODGING-HOUSE SANITATION.—The Board of Health in New York has been taken to task quite severely by the sanitary police for its failure to enforce the laws requiring a certain number of cubic feet of air for each lodger in the licensed lodging-houses of the city.

It is said that about half the houses are conducted with entire disregard of the law, and the Board of Health does little to enforce it. About three hundred judgments were obtained last year against persons for infractions of the sanitary laws of various kinds, but only three of these were satisfied. This remarkable result was brought to the attention of the grand jury some months since, and was criticised by them strongly; but still little was done to improve matters.

USE OF HYDRASTIS IN DYSPEPSIA.—Mr. A. G. Auld (in the *Lancet*, November, 1885, p. 885) speaks very positively of the specific influence of hydrastis in small doses in that form of dyspepsia common among females, where there is pain and sinking at the epigastrium, with nausea and constipation, associated with general debility, nervousness, wandering pains, and possibly leucorrhœa. The dyspepsia of phthisis and cancer is also amenable to the drug, as well as that form of indigestion resulting from alcohol. A very valuable editorial article on the use of hydrastis in various diseases is published in the *Brit. Med. Jour.*, August, 1880, p. 746; vide *Medical Digest*, Sec. 470: 3.—*London Medical Record.*

HYOSCYAMINE HYDROBROMATE, and also other products of Merck's laboratory, are imported and sold by Messrs. Eisner & Mendelson, of this city, who import from sixteen thousand to twenty thousand marks' worth of Merck's chemicals every month. This announcement is made in justice to an enterprising Philadelphia firm, because in a paper recently published in these columns it was implied that those who required these drugs would be obliged to go to New York for them. They are also to be found at our leading retail drug-houses.

LOCAL CAUSES OF FETID BREATH.—Chronic follicular tonsillitis, ozæna, and catarrh of the tongue are, according to McBride, prominent among the local conditions producing bad breath. The catarrh of the tongue which often accompanies dyspepsia may be successfully treated by applications of nitrate of silver dissolved in nitrous ether. Michel has recommended concentrated acetic acid for this purpose.—*Edinburgh Medical Journal.*

POST-PARTUM HEMORRHAGE.—In the *Lancet*, a correspondent writes that, being engaged to attend a patient who was accustomed to severe flooding after labor, he gave, in anticipation of hemorrhage, five grains of gallic acid twice a day for three weeks. So soon as the placenta came away no more blood was lost, though in previous confinements almost fatal flooding had followed, in spite of every treatment.

NEU-YORKER MEDIZINISCHE PRESSE.—A new monthly medical journal has been started in New York, as the special organ of the Medico-Chirurgical Society of German Physicians of the City of New York and Vicinity. It is ably conducted, and will be welcomed by German physicians.

AN extract from Ziemssen's Cyclopædia, by the celebrated Professor Juergensen, on Catarrhal Pneumonia, as appearing in advertising columns of this issue, may be of interest to our readers.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 3, 1886, *TO JANUARY* 16, 1886.

COLONEL THOMAS A. MCPARLIN, SURGEON.—Now awaiting orders in New York City. Ordered for assignment to duty as Medical Director Department of the Platte, on January 24, 1886. S. O. 5, A. G. O., January 7, 1886.

MAJOR CHARLES E. GODDARD, SURGEON.—Died at Fort Yates, Dakota Territory, January 4, 1886.

CAPTAIN CURTIS E. MUNN, ASSISTANT-SURGEON.—Ordered from Department of the East to Department of the Columbia.

CAPTAIN WILLIAM C. SHANNON, ASSISTANT-SURGEON.—Ordered from Department of the Platte to Department of the East.
S. O. 4, A. G. O., January 6, 1886.

FIRST-LIEUTENANT W. D. MCCAW, ASSISTANT-SURGEON.—Relieved from duty at Fort Lyon, Colorado, and ordered for duty at Fort Leavenworth, Kansas. S. O. 1, Department of Missouri, January 4, 1886.

LIEUTENANT-COLONEL EBENEZER SWIFT (Retired).—Died near Hamilton, Bermuda, December 24, 1885.

PHILADELPHIA, FEBRUARY 6, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE.

HOSPITAL COLLEGE OF MEDICINE, LOUISVILLE, KENTUCKY.

SERVICE OF DUDLEY S. REYNOLDS, M.D.,
Professor of General Pathology, Hygiene, and Diseases of the Eye and Ear.

Reported by ALLEN KELCH, M.D.

CASES ILLUSTRATING DEFECTS OF REFRACTION, WITH REMARKS.

MRS. C., æt. 38, has worn glasses fourteen years. She has never been able to see fine type, she says. She considers herself blind in the left eye, being able to see light only. She cannot tell a man from a woman at any distance with this eye. She has frequent attacks of harassing sick-headache, lasting for several days at a time. She is often nauseated and made sick by attempts to read or to sew. She cannot go in the street without glasses. Suspending her accommodation with homatropine, the glasses she wears enable her to read $\frac{20}{LXX}$ with the right eye and nothing with the left. After careful testing of the right, it was found that she could see in meridian 105° with $+\frac{1}{30}$, $\frac{20}{XX}$. Revolving the disk to 15°, she still saw $\frac{20}{XX}$. Removing the stenopaic disk, $+\frac{1}{30}$S allowed the patient to see $\frac{20}{LXX}$ only. Going over this several times without obtaining a different result, I placed two cylinders, each $+\frac{1}{30}$, with their axes at right angles before the eye, and instantly the patient saw $\frac{20}{XX}$. This, so far as I know, is the first symmetrically quadratic eye which has been fully corrected.

Testing the left eye, I was able to develop $\frac{20}{L}$ with $+\frac{1}{24}$ cylindrical axis 95°, combined with $+\frac{1}{12}$ spherical. Considering that this eye had never before been able to distinguish objects, not even to recognize the difference between a man and a woman at arm's length, I regard this result as being quite remarkable. The lady is quite intelligent, and is the wife of one of our most prominent ministers. The correcting-lenses being constructed after the formulæ above stated, the patient is now able to read the smallest type and to see all ordinary objects, and, in fact, enjoys not only normal acuity of vision, but perfect comfort in the use of her eyes.

This case is presented for the purpose of directing your minds to the consideration of defects of refraction in the eye. She had been to see a number of the most prominent specialists in the country, each of whom prescribed glasses. I took the pains to measure the glasses which she said suited her best, and which she had long worn, and I found the one for the right eye compounded as follows: $+\frac{1}{24}$c axis 75°, combined with $+\frac{1}{18}$c. In the left eye she had $+\frac{1}{18}$c axis 100°. For what reason this latter glass was prescribed I was not even able to conjecture, as the patient could see no object with it whatever. With the combination just stated she read $\frac{20}{LXX}$ with the right eye, whereas with two + cylinders—each of only $\frac{1}{30}$—set at right angles, the one at 105° and the other at 15°, she actually saw $\frac{20}{XX}+$.

Case II.—The gentleman before you—Mr. S., of Mississippi—wrote me some time ago that he had long been the subject of granular lids, and had been treated by quite a number of physicians in that section of the country, and went on to say that he was able to read for a short time in the day only. He was the subject, on any prolonged attempt at study, of very severe headaches, often confining him to bed, and sometimes to a dark room, for several days at a time. He wished to know the prospect of recovery in case he should come to Louisville. I wrote him that I doubted his having granular lids, but that nothing short of personal examination would enable me to form an intelligent opinion of his case, and advised him to come. He arrived in the city Saturday at noon. When he called at my office, on everting the lids I found hyperæmia,—mere suffusion of the conjunctiva lining the lids, without any evidence whatever of inflammation.

Suspending his accommodation, I found him utterly unable to distinguish any object on the test-card at twenty feet. He is here now at my special request, that you may witness the details of determining the state of his refraction. You observe this instrument, which has two catch-frames, with a sliding arrangement, so as to approach or separate at will. Each of

these catches has three grooves just suited to hold the lenses in Nachet's test-case. The faces of each of these semicircles are graded in degrees from 0 to 180. They represent half-circles revolved to the right. Placing Donders's stenopaic disk in the central groove and revolving it so as to bring the slot directly into the vertical meridian, and placing, as you see, $+\frac{1}{24}$ in the outer groove from the patient's eye, he sees $\frac{20}{XX}$. Revolving the disk to 180°, he is not able to see any character on the card. By experiment, you observe that with $-\frac{1}{24}$ he reads $\frac{20}{XX}$ in this meridian. Now, how shall we construct a spectacle-lens which shall represent the combined powers of these two lenses? The answer is simple. Of course the piece of glass out of which the lens is to be made has two surfaces, and we shall have one of these ground to represent $+\frac{1}{24}$ axis 180°, and the other at right angles to represent $-\frac{1}{24}$. Thus the combination is completed. Fortunately for Mr. S., you observe, the left eye is precisely like the right in its abnormal refraction. The next step is to determine the distance between the pupils and the height of the bridge of the nose. He measures two and three-eighths inches from the centre of one pupil to the centre of the other, as he gazes steadily at the bridge of my nose about eighteen inches from his face. Now, if he looks at the wall over my head the distance between his pupils is two and a half inches. This is a very important matter for consideration in ordering compound lenses, or in fact any kind of lens for the purpose of reading and out-door use. In reading the eyes converge, and in gazing at distant objects the eyes permit the lines of vision to lie in parallels. The difference between the adjustment of the eye for distant objects and for near objects is generally about one-eighth of an inch. The glasses for this gentleman for reading should be two and three-eighths inches between the centres, while if he wears them for out-door use they are likely to fatigue the eyes unless he has another pair set in frames two and a half inches between centres. There is nothing peculiar about the bridge of his nose. The ordinary curve found in oval spectacle-frames, therefore, will answer his purpose. As he has a moderately long neck, and is able to raise the chin and toss the head back with ease and comfort, the same character of frame which he uses for reading may be worn for distant vision. If the bridge of the nose were very high he would require a deeper curve in the frame for reading than for distant vision, while if it were very low it might be necessary to have no groove in the bridge at all in the frames for distance, while those for reading might drop down to the cheek without touching the nose at all.

There is a serious objection to setting lenses in the pinch-nose frames, because they are seldom adjusted in such a manner as to permit the lenses to lie directly before each eye, that the patient may see through the centre, and because they are never even approximately in the same plane.

It requires a great deal of care to adjust spectacles properly. The eye must see through the centre of the lens, and the lens must occupy a plane at right angles to a line drawn from the centre of the pupil to the surface of the object, and the object itself should lie in a plane parallel to that occupied by the lens and at right angles with the line of vision. The light should always come from above and to one side, or, as it is commonly expressed, over the shoulder. The glasses should be as close to the eye as possible without touching the lash. If for reading, the two glasses should not be in the same plane, but should intersect the line of vision precisely at right angles. This may be accomplished by so bending the bows as to make them press firmly against the sides of the head, causing the bridge of the frame to spring just sufficient to place each lens in the desired position before each eye, whereas, on the other hand, in adjusting glasses to see distant objects the two lenses should occupy the same plane.

If these rules be not observed, any discrepancy in the distance between the centre of the lens and the axis of vision will overtax the muscles of the eye to overcome the prismatic effect of the abnormally adjusted lens; or if the muscles are not able to resist the prismatic effect thus produced, double images appear to harass and annoy the patient. It may seem to be a great deal of trouble to observe all these details in the mere matter of adjusting spectacles; but a careful observation of them will be necessary to secure the best results. It is a matter of some importance in prescribing glasses that you should be

able to obtain the glasses for measurement, and to show the patient the proper methods of adjustment. In a carefully-recorded experience extending through nearly a quarter of a century, I can truthfully say that not one in three hundred will adjust the glasses properly without instruction, and that it is rare indeed that any one, except a well-trained, practical optician, can fill even the simplest order for spectacles correctly. You are to understand that jewellers are not opticians, and that the spectacles peddled about the country, as well as those kept in all notion-stores and jewelry-establishments, are exceedingly unreliable. They are sold by numbers, and it is the rarest thing to find the two lenses in one frame of exactly the same refracting power. It is rare also to find lenses symmetrically ground, and rarer still to find them made of a good quality of glass, which will not become colored on exposure to the light. The proper material for spectacle-lenses is crown glass, and not quartz, or pebble, as it is sometimes called.

TREATMENT OF NASAL POLYPI BY INJECTIONS.

Case III.—Mr. William M., æt. 28, came here two weeks ago with a peculiar voice, which at once suggested obstruction of the nose. Examination revealed chronic muco-purulent inflammation in the right nostril: the left was completely filled with gelatinoid polyps.

Nasal polypus has long been a part of *opprobria medicorum*. Various kinds of forceps have been invented for the purpose of seizing the tumor and drawing it out bodily. This, of course, could never succeed in removing the entire tumor with its pedicle, yet it always succeeded in doing more or less damage to the previously inflamed portions of the nasal membrane, and even denuding, wounding, or even crushing the turbinated bones. Different kinds of scissors have been devised for cutting off the pedicle, but, as with the negro who was congratulating himself upon the feast of broiled rabbit, the game has not yet been caught.

If the pedicle could be reached with unerring certainty, there could be nothing more simple than to clip it asunder with scissors. Unfortunately, however, the pedicle is seldom in sight.

Different kinds of snares and écraseurs have afforded temporary joy to their too enthusiastic inventors, with a modicum of comfort to the patient. Quite recently I was amused to read an account of a novel method of removing polyps from the nose. The inventor of this new plan treated the subject as though the only object in view in the treatment of such cases was simply the mere expulsion of the polypus. Accordingly, he used an instrument similar to Bellocq's canula, and, placing a quantity of old linen torn into strips in the loop, he drew this mass of old rags up through the posterior nares, when, by making a sudden jerk, he announced that the polypus could be shot out of the nasal passages, much as the wad is expelled from a popgun.

He seemed to regard this as a great achievement in surgery. The sweet simplicity which apparently clustered about the ignorance and the illiteracy of the author of this novel device is, to my mind, in charming contrast to the able adventurer who, with a galvano-cautery, undertakes to clean out turbinated bones, polypi, and all with a simple touch of the electric fire.

To be plain, gentlemen, the treatment of polypus of the nose is a serious matter. It requires much time and patience not merely to remove a polypus, and in that way produce some temporary relief to the patient from the mechanical obstruction to nasal respiration, but to change the nutrition of the membrane upon which these pestiferous growths are developed. Swelling in the nasal membrane, causing close and firm apposition on opposite sides of the crypt, causes accumulation of mucus in the follicles. One or more of these presently dilate, and, once the connective-tissue walls begin to yield, it presently ruptures, and a commingling of mucus and lymph rapidly distends the submucous cellular tissue, until presently a well-defined pedunculated growth is made to project into the previously open space. The nature of the pressure may cause two or more of these growths to develop near the same site, and, unless obliteration of the sac or its complete extirpation be practised, rapid reproduction of the growth must necessarily follow.

Considerable experience with different kinds of caustic or other injecting-fluids thrown into the body of polypoid growths in the nose has gradually led me into the habit of relying almost exclusively upon this means of destruction and removal.

I usually begin, as I did in this case, with

the injection of from one to three minims of liquefied pure carbolic acid, which I throw into the body of the tumor through the hypodermic-syringe needle, made especially long and bent at an angle of twenty-five degrees near the point of attachment to the barrel. This needle is straight from the point back three and a half inches, and is very convenient for the purpose of injecting nasal polyps. I have injected Mr. M.'s polypus in two different places on previous occasions. You now observe that he is able to breathe freely through the left nostril, and exhibits in his voice none of the signs of obstruction which characterized his first appearance here. There are still, however, a few little irregular fringe-like projections from the lower margin of the middle turbinated bone. With some difficulty reflected light may be focused at the point where these bodies are situated, and, as you see, I am now able to inject the liquid carbolic acid without permitting any of it to run down into the pharynx or forward into the nose. While the point of the needle is still within the body of the largest one of these polypoid masses, he says he feels but slight pain, not at all severe, and, by waiting fifteen or twenty seconds after the injection of the fluid, the needle may be slowly and cautiously withdrawn without letting out any of the carbolic acid, and without producing any hemorrhage beyond the slight oozing of bloody serum. The carbolic acid instantly coagulates the contents of the polyp, while the investing membrane is quickly inflamed, and in about forty-eight hours from the time of the injection it is usual for the main part of the injected growth to come away *en masse*, completely sphacelated.

The spray through a glass tube of the saturated ethereal solution of iodoform may in many instances be advantageously employed just after the slough has separated. Where the discharge is very tenacious, the use of tannin dissolved in Listerine is desirable. It may be employed in saturated solution with a mop made of cotton-wool rolled upon the end of a probe, so as to pass readily to the exact spot which it may be desired to touch, or the solution may be diluted with distilled water in any proportion and sprayed into the nose. It coagulates the lymph instantly, and is not followed by any painful irritation. It is especially useful in cases where the discharge is profuse and there exists a tendency to form such accumulations as would obstruct the passages and shut out the air from the nasal membrane.

It is probable that the injection practised a moment ago will be the last Mr. M. will require. Yet it will be necessary to touch the points where the pedicles grew from the surface of the membrane, at different times, with pure carbolic acid, or, if the tendency to vegetation resists that, a little chromic acid carefully applied, taking care always to touch no other part than that which it is desired to destroy by the caustic.

Some cases of polypus exhibit a tendency to frequent hemorrhages, especially of the remaining pedicle after the body of the polypus has been destroyed by caustic. Injection into the bleeding pedicle of the officinal compound tincture of iodine, or of iodine in solution, will be followed by rapid shrinking of the vascular mass and permanent relief of the hemorrhagic tendency.

In the case of Mr. M., a powder, compounded according to the following formula,—

℞ Sodii boratis, ʒj;
Sodii chloridi, ʒij;
Cubebæ, gr. v.
M. Ft. pulv.,—

shall be used by the patient as a snuff at intervals sufficiently short to prevent accumulations of matter in the nasal passages. This powder creates no pain or other uncomfortable sensations, and may be freely snuffed up into the nose, drawn back into the pharynx, and hawked out.

ORIGINAL COMMUNICATIONS.

FOREIGN BODIES IN THE VITREOUS.*

BY E. MEIERHOF, M.D.,

Professor of Diseases of the Eye and Ear in the Baltimore Medical College.

F. S., aged 22, sheet-iron worker, was engaged in riveting boiler-plates, when a piece of steel from the button-set used in forming heads on rivets flew off, striking the outer and upper ciliary region about two mm. behind the sclero-corneal margin. I saw the patient about an hour after the accident, and

* Read before the Clinical Society of Maryland.

the eye presented the following appearances. At the point where the eye was struck, a wound, causing a bit of iris to prolapse in the opening, was seen; the anterior chamber was slightly cloudy, but it was impossible to see much beyond this, as the vitreous was bloody. The patient complained of little or no pain. The eyeball was quite soft, and vision equalled quantitative perception of light. The patient was ordered a one-per-cent. solution of sulph. atropine, and the application of iced pledgets of linen to the external surface of the lids, and to remain at rest in a horizontal position in a darkened room. The next day the eye was improved in its appearance, the night previous having been spent without any pain. The vitreous was slightly clearer; a number of small floating bodies, supposed to be coagulum, indistinctly seen in the vitreous. Vision equalled fingers at four feet. On the fifth day a dark-looking body was seen in the anterior part of the vitreous. The prolapsed iris was reduced, and the eye had lost much of its softness, with the vision $\frac{14}{200}$. On the sixth day the dark-looking object had changed to a bright, reflecting, rectangular-shaped piece of metal, apparently five mm. by three mm., the thickness of which it was difficult to estimate, except judging by the knife-like wound made in piercing the sclera. The foreign body was apparently just behind the lens, resting in the lower part of the vitreous. It moved freely when the eyeball was rotated. Vision $= \frac{20}{200}$. The retinal vessels could be seen indistinctly in the erect image in outer field only. The lens does not appear to have been displaced or injured. The day following this the foreign body seems to be surrounded with a veil. An operation for the removal of the piece of steel was advised immediately upon discovering it, to which the patient and his friends assented two days afterwards. Upon the tenth day after the infliction of the injury an operation after the following method was performed. A four-per-cent. solution of the hydrochlorate of cocaine was instilled into the conjunctival sac after the regular method. As the position of the foreign body when at rest was on a plane parallel to the iris, it was deemed best to make the scleral incision in such a manner as to produce the least disturbance of the contents of the eye. With the kind assistance of Drs. S. Frank and H. M. Simmons, I made an incision parallel to the edge of the foreign body, on the outer and lower portion of the globe, about four mm. behind the sclero-corneal margin, with a Von Graefe cataract-knife. The incision made was about five mm. in length. The tip of Gruening's permanent magnet was introduced into the opening made, which at once attracted the metallic body to the opening; and upon seizing the body with a pair of fine clot-forceps it was found impossible to draw the chip through without considerable dragging: so it was deemed advisable to enlarge the incision, which was done with blunt-pointed scissors. The second attempt was again successful in attracting the chip and drawing it easily through the opening. The incision, amounting to about six mm. in length, was closed by means of a deep conjunctival suture, which was sufficient to keep the edges of the wound in approximation. There was comparatively no hemorrhage, but the incision gave rise to considerable pain. Cocaine was of use only in allowing the speculum to remain in position without discomfort, allowing the conjunctiva to be seized, and preventing hemorrhage. The patient was kept in bed, with the resumption of iced pledgets and atropine. At night $\frac{1}{4}$ grain of morphine was ordered, to insure sleep. The case went on to recovery, so that at the end of three weeks the vision in the injured eye equalled $\frac{20}{40}$, or one-half, but the eye has never recovered its normal tension. The piece of steel, as will be seen, is quite large in its dimensions, being about 3 mm. by 5 mm., and weighing 68 mgr., or $1\frac{18}{100}$ gr.

It is a pity to throw a wet blanket on this brilliant result, but nevertheless it is my duty to state that two months after the operation my patient paid me a visit, complaining of the loss of vision in his injured eye, which upon inspection was found to be due to an almost complete detachment of the retina. He says it followed a drinking-spell one day when he imbibed about a pint of whiskey, which he states did not intoxicate him. There was at the time quantitative perception of light in the outer field. Whether the drinking fostered the retinal lesion it is impossible for me to say, but it is possible the detachment may have been produced by cicatricial changes caused by the injury and that following the operation, besides there being fluid vitreous. I omitted to mention a little experience with the wound. As stated before, a deep conjunctival suture was inserted, which was removed on the third day, as it did not seem to be of any further service; on the fifth day, there being a bead of vitreous which seemed to keep the wound from uniting, I inserted a second suture as before, with the result of having the wound to close two days later.

In June last there appeared one of the most authoritative articles on this most important subject by Professor Hirschberg, of Berlin, who has given us his splendid monograph "On the Electro-Magnet in Eye-Surgery," based on the experience of thirty-two cases of his own, together with

that of all the cases reported up till the issuance of his work. What had been written before on this subject was generally the report of cases by a number of operators; but the experience of Hirschberg is very extensive. His monograph contains so many valuable suggestions that I thought it would not be amiss to mention some.

He says the indications for operating cannot be precisely defined, except that the operation is best done early for the removal of foreign bodies in the eye. If a patient is seen in the first stage, which is within twenty-four hours after the injury, it is best to operate without delay. If the opening lies in the cornea, and especially near its margin, a scleral section is best; and if the opening lies in the sclera at a proper distance from the cornea, the tip of the magnet may be at once introduced, provided the foreign body can be seen in the coagulum or through the cornea, enlarging the scleral section if necessary. If a scleral section is necessary, he advises the patient to be anæsthetized, on account of the great pain caused by the operation, which was the experience in my case. He advises a meridional section (as is usually done) to be made in the lower outer portion of the globe, measuring with a compass a distance of eight mm. from the margin of the cornea, and while an assistant rolls the globe upwards with a pair of strong forceps, plunges a Von Graefe knife several mm. deep into the vitreous at the distance mentioned, for the purpose, as he says, of opening a path to the foreign body through the vitreous, and then finishes the section by enlarging the incision towards the equator of the eye for a distance of six mm. The magnet is then introduced and left inside for a few seconds, and, if the diagnosis is correct, withdrawn with the foreign body attached. The conjunctiva is sutured over the incision and antiseptic dressings applied.

He speaks of the difficulties met in making a diagnosis: the chief one is in discovering the position of the foreign body. The second stage he defines as the stage of irritation, and up to the time when the latter may have increased to circumscribed or diffuse inflammation of the vitreous. The third stage is that when a new inflammation is excited months or years after all previous irritation has ceased, caused by a change in the location of the foreign body. In the second stage it is advised to operate at once. Regarding the third stage, he mentions a case in which, despite the presence of iron in the eye for sixteen years and a cataract and well-marked irido-cyclitis, the finest type could be read after the removal of the iron with the magnet.

When shall we extract iron through a linear or flap section at the margin of the cornea? (*a*) When the patient is young, the foreign body not far behind the lens, the cataract mature, and irritation has ceased; (*b*) when the lens has already been removed, or has been absorbed, and when only a thickened capsule is left behind.

If the foreign body is small and the eye is seen in the first or second stage, and the lens is only partially opaque, the scleral section is preferable; later, we can extract the lens when mature.

If the eye is ruptured for a distance of six to ten millimetres, the globe collapsed or half full of coagulated blood, the magnet performs a genuine surgical triumph in withdrawing a large piece of steel weighing from two hundred to five hundred milligrammes; but vision is not restored. A case is reported in which, despite panophthalmitis, the eye was saved after removal of a piece of iron weighing thirty-one milligrammes, and in another the same result was obtained after removal of a large piece of iron weighing one thousand and fifty milligrammes. As to the form of magnet, it is a well-settled fact that the electro-magnet is the one most useful and reliable: the permanent magnet is of limited utility only, portability being the greatest thing in its favor. There are several forms of electro-magnets which are useful, but Doerffel, of Berlin, makes an apparatus of zinco-carbon elements in a glass jar holding about one litre, the fluid to be renewed from time to time, and the energy tested before each operation, which seems to meet every indication. The apparatus will lift a piece of iron weighing five hundred grammes.

In the long list of extractions from the vitreous, Hirschberg has succeeded twice in obtaining excellent vision, once a remnant of vision, and twice in preserving the shape of the globe,—a great difference in favor of the electro-magnet, when, before its use, he did not succeed in saving a trace of sight when an attempt, either successfully or unsuccessfully, was made to remove

pieces of iron from the vitreous by purely mechanical means.

There is no doubt in my mind that the successes in the operation for removal of foreign bodies from the vitreous are overstated; that is, so far as the permanency of the result is concerned. If we could keep trace of the subsequent histories of cases operated upon, it would be found that the number of successes was diminished on account of later complications, for in the reports of some of the cases some time after the operation, detachment of the retina was reported to have taken place. We have made great strides in the treatment of traumatism of the eyeball and its contents resulting from injuries by foreign bodies, even though useful vision is not always preserved. Yet we should take into consideration the great danger an eye runs when containing a foreign body in its interior. Even though a long period may have elapsed and its action remained dormant, it nevertheless is liable to light up a most serious inflammation, involving not only the injured eye but also its fellow-organ. It is strange that more accidents of this character do not occur, considering the enormous number of people who are daily exposed in pursuing their avocations in the various mechanical arts. Means have been suggested for the prevention of these injuries, but it seems that such suggestions are practically ignored.

ARTIFICIAL CLIMATIC EFFECTS FOR "STAY-AT-HOMES."

Read before the Philadelphia County Medical Society, December 9, 1885,

BY SOLOMON SOLIS-COHEN, A.M., M.D.,

Chief of Clinic, Out-Patient Medical Department, Jefferson Medical College Hospital.

THE benefit to be derived by consumptives from prolonged residence or temporary sojourn in localities where the climatic conditions are favorable is a matter of every-day observation. Not all, however, of the army of sufferers—an army whose death-roll in the city of Philadelphia is more than one-fourth of all the adult deaths—are able to avail themselves of a change of climate. What can we do for those, the vast majority, whose domestic ties, business interests, or lack of means preclude the possibility of leaving home? Granted that the atmosphere of Florida, or Colorado, or the Adirondacks, or California, possesses health-restoring properties, would it not be desirable if we could so modify the atmosphere in which our patients live as to bring, as it were, Colorado or Florida or the Adirondacks to their dwellings? Or would it not be still more desirable if we could combine the most beneficial qualities of different climates, and so adjust them to the individuality of each case as to give the stay-at-home the benefits of Colorado, Florida, and California at one time, and in the midst of his family? The answer to these questions is an emphatic affirmative. Can we do this? To the latter question our affirmative must be qualified. We cannot accomplish all that we may desire: still, we can accomplish much. We cannot, of course, change out-of-door conditions. We cannot cause the sun to shine when forces, often beyond our ken and always beyond our control, have wrought it otherwise. We are as powerless to divert the course of the storm-cloud as King Knut to stay the sea. Therefore, we cannot send our patients out into the open air continuously,—a highly-appreciated advantage of certain climates, both warm and cold. Neither can we have our patients stay at home and receive the benefits conferred by change of scene, rest from ordinary avocations, freedom from annoying surroundings, and the other collateral advantages which going from home affords. But we can, by artificial changes of atmospheric pressure about our patients, or by modifications of the pressure of the air breathed by them, and the impregnation of the respired air with certain volatile medicaments, produce effects which approximate more or less closely some of the effects produced by residence in elevated regions at low barometric pressure, or at the sea-shore, or in pine regions, or among any of the other atmospheric qualities which may be considered beneficial in particular instances. While we cannot by these measures, which must be conducted intermittently and in-doors, rival a continuous life in the desired atmosphere with the concomitant benefits of out-door exercise, yet in certain cases we can more than compensate for this defect by the accuracy with which we can fit the properties of our artificial atmosphere to the requirements of the case in hand, by the ease with which

we can combine different desirable qualities not always found combined in nature, by comparative independence of the meteorological variations from which even the most favored climate is not exempt, and by our power to produce certain local effects to which climate alone is inadequate. And in all cases where going from home is out of the question, it certainly seems our duty to do what we can towards affording a modicum of that relief whose entirety is denied by circumstances.

The means at our disposal for the production of these artificial climatic effects are the compressed air-bath or rarefied air-bath; the intermittent inhalation of compressed air, or of rarefied air, or of ozone, oxygen, nitrogen, or nitrous oxide, or of a mixture of these gases with each other or with air; and the continuous inhalation of balsamic or antiseptic vapors, such as terebene, eucalyptol, benzoin, creasote, thymol, iodine, and their congeners. The air-bath, whether compressed or rarefied air be the medium in which our patient is immersed, whether the classical cabinet of Tabarie or some of the more recent modifications thereof be the device employed, necessitates the construction of a costly apparatus, and consequently cannot well be employed except at an institution specially devoted to such purposes. I shall not, therefore, dwell upon this or any other of the expensive plans for accomplishing similar ends, but shall present only methods to which every physician can readily resort.

Hauke, in 1870, constructed the first portable apparatus for the administration of compressed air by inhalation, and since his time many others have devised apparatus for the same purpose, the best of which is probably that of Waldenburg, modelled after the spirometer of Hutchinson. It consists of two cylinders, one of which, inverted, slides within the other, its motion being controlled by weights and pulleys,—in fact, the ordinary gasometer. The outer cylinder being filled with water, the air within the inner cylinder can be compressed by means of weights placed on top of it, or rarefied by means of weights suspended from the pulleys. Various attachments, gauges, scales, etc., permit of accurate clinical and physiological application and observation. Waldenburg's machine or Schnitzler's modification of it is expensive, is difficult to obtain on this side of the Atlantic, and is too cumbersome to be transported to and from a patient's house. Setting aside expense, for office use I do not think it can be improved upon. The little apparatus I have here (Fig. 1),

Fig. 1.

Cohen's compressed-air apparatus.

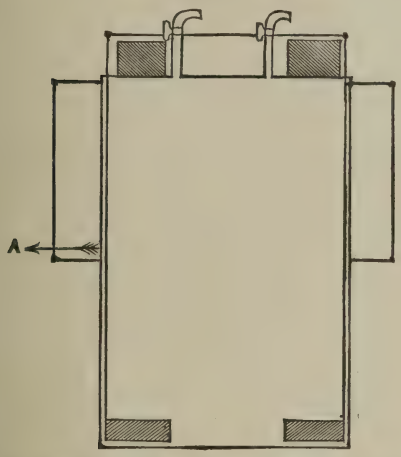
and which I explained in detail to the Society last year, is the outcome of a series of personal experiments* with many different devices. It is practically a Waldenburg apparatus cut down in size and in price. The original features consist of the manner in which the inner cylinder is weighted, and the manner in which the air is introduced. Instead of sucking the air into the inner cylinder by lifting the cylinder with weights, we pump it in from a foot-bellows. The equilibrium of the inner cylinder, which has neither flanges nor pulleys, is maintained by two weights placed upon shelves at the bottom (Fig. 2).

For detailed description and illustration, I would refer to last year's Transactions of this Society. This apparatus can be used only for administering inhalations of compressed air. It is not available if rarefied air be desired. I have had one of these machines in constant office use for more than two years, and find it perfectly satisfactory. Some few have been purchased for home use by patients residing out of town, and, as I have heard no complaints, I presume that they answer the purpose. The patient should stand, if able, while inhaling, with the head thrown

* I am indebted to Mr. Charles Richardson, of Queen & Co., for valuable assistance.

up and the shoulders drawn back. Sometimes it is advisable for the physician to

Fig. 2.



Section showing the manner of weighting. At the level of arrow *A* there is a row of perforations, to permit the escape into the overflow-tank of the water displaced by pressure.

gently press the shoulders backward or forward in harmony with the acts of respiration. From fifteen to thirty, or even forty, respirations can be taken continuously, after which there should be a rest of at least ten minutes before repeating the process. Two or three sets of respirations are enough for one visit. One or two visits a day are usually sufficient. The pressure employed varies from one-eightieth of an atmosphere (additional) to one-thirtieth of an atmosphere, the average being one-sixtieth of an atmosphere.

If desired to medicate the air, we pass it, as I show here, through a Wolff bottle, in which is placed, in addition to water, a drachm or two of the medicament desired,—in this case terebene. The little perforated zinc respirator* (Fig. 3) which I exhibit is essentially the same as that devised by Dr. Burney Yeo, of London, probably the best that has ever been offered to the profession. The sponge which is secured in front is saturated or impregnated with the desired solution, and the patient wears the apparatus for a number of hours continuously, at such intervals as convenience or necessity may dictate. With this modified Waldenburg, a Wolff bottle, a Yeo respirator, and a few ounces of terebene, creasote, eucalyptol, ethyl iodide, tinc-

give our patients a very satisfactory substitute for the pneumatic effects of change of climate. Add to this armamentarium a

* As manufactured by Mr. Louis Genois, pharmacist, of this city, the respirator is slightly modified, according to a suggestion of Dr. J. Solis-Cohen, from Dr. Yeo's original pattern.

reservoir of oxygen gas and one of nitrous oxide, and we have all that can be desired in the way of respiratory therapeutics, in the vast majority of cases. A few words now as to what we can accomplish by some of these various methods.

As the subject of the evening is pulmonary consumption, I shall speak only in relation to that disease, and, as I said before, only of methods easily available.

The inhalation of oxygen gas, as a continuous and sole reliance, has failed in the experience of my preceptor and in my own experience to be of any permanent benefit. Resorted to occasionally, in the course of treatment by compressed air, to overcome temporary depression, or administered daily in connection with compressed air, it does seem to heighten the good effect; and, if we may judge of its action beyond sight by its action upon regions within laryngoscopic inspection, it may be considered to hasten the reparative—*i.e.*, cicatricial—process in softened or ulcerated areas. In the presence of active febrile process, oxygen is contra-indicated.

Inhalations of ozone, theoretically desirable, are highly spoken of by some observers and condemned by others. The reported effects are so contradictory that in the absence of personal experience I can simply allude to the subject.

Inhalations of nitrogen gas are said to diminish febrile action, to have a sedative effect upon an excited heart, to check cough and night-sweats, and to improve nutrition. I cannot as yet speak from personal experience. I have known valuable sedative effects, diminution of fever, and promotion of sleep, as well as temporary relief to irritative cough, to follow inhalation of a mixture of nitrous oxide gas and air.

The inhalation of compressed air distends unused air-cells and forces a proper expansion of the chest upon patients too weak to respire effectively unaided. In this respect it simulates, and indeed surpasses, residence at high mountain altitudes, where the rarefaction of the surrounding atmosphere relieves the pressure upon the thorax and permits expansion with less muscular effort. If at the same time that the patient inspire compressed air he is allowed to expire into rarefied air, the lungs can be better emptied, through relief from backward pressure, and subsequent inspirations are thus rendered deeper, the interchange of gases being at the same time greatly facilitated. In this way, the complemental air of inspiration being increased in quantity, and becoming, in fact, the tidal air, a greater amount of blood becomes exposed to an increased quantity of oxygen under pressure, the most favorable condition for absorption of oxygen by the hæmoglobin, and exhalation of carbonic acid is hastened. Thus depuration is favored and nutrition is increased. Regions of pulmonary tissue which have long been inactive are again brought into use, and healthy areas are stimulated to energetic function. Pent-up secretions, often decomposing, are stirred up, and finally expelled, reopening occluded lobules to the entrance of respiratory pabulum, and relieving the economy from the deleterious effects of the presence within an important viscus of effete and putrefying materials. The entire respiratory tract is subjected to a purifying and vivifying bath, and the muscular apparatus of the thorax undergoes a systematic gymnastic exercise. The effect upon the circulatory system of the modification of intra-thoracic pressure and the stimulation of intra-pulmonary capillary activity is to relieve tension and increase tonicity, steadying and strengthening the heart, which sends through both pulmonic and aortic systems an increased quantity of blood with lessened effort. These respiratory and circulatory effects reacting upon each other and upon nutrition in general, the ultimate result is an increase in vital capacity of the lungs often astonishing,—the clearing up of congested and occluded pulmonary areas, with in many cases absorption of inflammatory products,—and an increased power of both primary and secondary assimilation, as manifested by gain in strength and in flesh. The increased digestive powers permit us to resort with still further benefit to a system of hyper-alimentation by means of prepared foods, such as Reed and Carnrick's "beef peptonoids," or Favrot's, or Parke, Davis & Co.'s "powdered beef," the first-mentioned preparation being the best that I have come across for the purpose; and, what is a very important matter, the patient is able to ingest this increased food voluntarily, doing away with the necessity for resort to the tube of Debove, a method to which patients manifest repugnance, and in some cases unconquerable disgust, undoubtedly

beneficial though it be. I have tried forced feeding by means of the tube in two or three cases, but have been compelled to abandon it; while by the use of condensed aliments in connection with compressed air I have seen results as astonishing and as permanent as any reported to follow forced feeding. These condensed and predigested foods are to be taken in addition to the ordinary meals of the patient, the latter being properly regulated as to quantity and quality.

If at the same time that we force open the pulmonary alveoli and distend the lungs to their full capacity we impregnate the inspired air with some suitable vapor, we accomplish both systemic and local medication. The agent chosen should not be too irritating, and should be one which, either from empirical or physiological considerations, is known to be of benefit. Pine regions have long enjoyed favorable repute as resorts for consumptives, and the peculiar quality of the atmosphere of these regions can be very closely imitated by the employment of terebinthinate vapors, especially terebene, a derivative of turpentine. From some recent observations of Dr. J. Solis-Cohen, if the inhalation of terebene be followed by that of a moderate quantity of oxygen* the effect seems to be still more accurately reproduced. Possibly ozone would be better. The compressed air, or the oxygen, can ordinarily be employed only once or twice a day. The inhalation of terebene, however, can be continued indefinitely by means of the Yeo respirator, five or ten drops being placed upon the sponge, advantageously mixed with an equal quantity of spirits of chloroform. Terebene is somewhat irritating, but the chloroform modifies this quality. Another method of accomplishing continuous inhalation is to evaporate terebene or turpentine in the living-room of the patient, either from the surface of steaming water contained in a suitable vessel, or by means of some of the more elaborate apparatus which have been devised for this and similar purposes. The advantage of the respirator is that the patient need not be confined to one room. It can also, if the patient be bold enough, be worn in the street. Bold patients are rare.

* The oxygen may, if desired, be passed through a wash-bottle containing a small quantity of terebene, similarly to the compressed air.

Other drugs having the pine-wood effect are tincture of benzoin, oil of pine, oil of fir, and eucalyptol. These may be used in various combinations. Creasote is another drug of very great utility. Iodine and ethyl iodide are also of benefit in some cases, but these latter agents, despite the traces of iodine in maritime atmospheres, belong rather to the list of medicinal than to that of climatoid inhalations, and it is not of the medicinal treatment that I now desire to speak,—it being understood that, whether we send our patient from home in search of a suitable atmosphere or endeavor to bring that atmosphere to him, dietetic, hygienic, and medicinal measures should be instituted *secundum artem.*

THREE CASES OF REMOVAL OF THE OVARIES AND FALLOPIAN TUBES (TAIT'S OPERATION).

Read before the College of Physicians of Philadelphia, November 4, 1885,

BY W. W. KEEN, M.D.,

Professor of Surgery, Woman's Medical College of Pennsylvania, and Senior Surgeon to St. Mary's Hospital, Philadelphia.

THE following cases are put upon record as a contribution to an important operation, the usefulness of which is assured in certain cases, but the limitations of which have not yet been perfectly well defined.

Case I.—Uterine Myoma; Excessive Hemorrhage and Anæmia; Tait's Operation; Recovery and Cure.—Mrs. L., of New Jersey, æt. 42; married at twenty-eight; two children, the last born ten years ago; each eleven pounds; normal labors; no miscarriages; absolutely well and strong till three years ago, when her periods became gradually more prolonged and profuse. Now she is unwell three weeks out of every four, and the flow is often so severe as to saturate a napkin every fifteen minutes, besides large clots of blood. She is thoroughly blanched, weak, and anæmic.

November 25, 1881. Sent to me for consultation by Dr. Hollingshead. A tumor is visible in the hypogastrium the moment she lies down and the abdomen is exposed; sound enters six and one-fourth inches. The tumor is an interstitial myoma in the posterior wall, as large as a large fist, moderately tender and painful; no vegetations on the endometrium; no erosion of os; cervix not involved; uterus movable. Advised Squibb's extract of ergot (℥xxx–xl), hypodermically, daily into the abdominal wall for a month; if not

then better, advised Tait's operation, as all other means had been previously tried by her attending physician. She was unwell at the end of November, when the ergot was first used. It gave rise to great pain and considerable local inflammation, with nausea and vomiting, and had to be discontinued.

December. Again unwell; the intermenstrual period was freer from pain; but she was weaker and more blanched, and not able to come to the city; lost a large quantity of blood.

January 26, 1882. Came to the city; was so blanched that, had she closed her eyes and folded her waxy hands, she could easily have been mistaken for a corpse; weight one hundred pounds. Treatment: iron, quinine, milk-punch; food every two hours.

28th. Taken unwell; period lasted till February 2; used twenty-eight napkins, besides passing a number of large clots. Bad neuralgia of face; morphia (one-eighth grain) hypodermically failed to relieve, but water similarly given lessened it. Eats but little, on account of pain.

February 3. Dr. R. P. Harris saw her with me, and concurred in advising the operation. Temp. 98.5°; pulse 80, feeble; heart normal, but weak; no change in uterus.

9th. Operation, 12 M.; antiseptic method with carbolic acid, including the spray; bladder emptied. Duration of operation forty-five minutes. Ether (f℥viiss) used; incision four inches long, in median line, from pubes half-way to umbilicus; no vessels tied.

On opening the abdomen, a moderate amount of serum escaped. On account of the high position of the uterus, the ovaries were readily found. Each pedicle was transfixed with a double carbolized-silk ligature close to the uterus, the upper including the Fallopian tube, and, after ligature, the tubes and ovaries were removed. The left ovary showed a recent corpus luteum; it had a few small cysts, and was cirrhosed in part. The right had one cyst two inches in diameter, and several smaller ones. The right tube was cystic just at the cervix uteri; it contained a serous fluid. The veins were very large; no bleeding requiring a ligature occurred. The ligatures were all cut off short; four deep and two superficial sutures: the former, including the peritoneum, closed the wound. Dressed with carbolized gauze.

Immediately after the operation her pulse was 120 and feeble. Hot-water bottles were applied, and brandy was used hypodermically several times with good effect. She vomited only once up to 3.30 P.M., when her pulse was 93, temp. 97.2°; very small quantity of food and stimulant every twenty minutes. 7 P.M. Pulse 100, temp. 99.6°; has had some pain; feels stronger. 11 P.M. Temp. 100.8°.

10th. Slept but little, but is comfortable; temp. 100°.

11th. Temp. 98.4°; considerable pain in the back at 9 P.M. last night, followed by a bloody vaginal discharge. In twenty-four hours has used sixteen napkins, moderately saturated. Water at 105°–110° ordered, which gave great relief.

12th. Has used twelve napkins; temp. 98.8°.

13th. Slept excellently; discharge has ceased; dressing changed (fourth day). It was barely soiled with very slight oozing from the operation; no pus; wound free from blush; union by first intention throughout; meat allowed.

15th. Several enemata having had no effect, and as she felt uncomfortable, the rectum was emptied mechanically of a large amount of impacted scybala.

19th. Redressed; wound healed; sutures removed.

22d. Sat up.

25th. The menstrual period was due on the 24th; has used two napkins to date; less than f℥ss blood on each.

March 17. Went home; weight one hundred and ten pounds.

24th. Menstruation due: had some backache; no blood; stayed abed three days.

June 6. Came to see me; brown as a berry; weight one hundred and thirty pounds; appetite good; strength nearly regained; each month had had slight malaise; no bleeding; uterine cavity three and three-quarter inches; myoma not perceptible, except by bimanual examination.

March, 1884. Rapidly regained full strength; weight has continued at one hundred and forty pounds; no bleeding; sexual appetite unimpaired; tumor entirely gone; uterus three inches.

Case II.—Severe Nymphomania, leading to Incipient Insanity; Menorrhagia; Tait's Operation; Recovery; Cure.—Mrs. B., of New Jersey, æt. 42, American; eight children, last born eight years ago; operated on by me successfully four years ago for lacerated perineum, and later another operation for severe hemorrhoids. Wife of a poor, ill-paid clergyman, and hence her life was a constant struggle properly to feed and clothe her large family. I have known her from childhood. She was always a most exemplary Christian woman.

Her head began to trouble her not long after the first operation, and she attributed it to the ether, which, however, she bore perfectly well in both operations. She had strange feelings, as if unconscious and in a fright or dread of ether, especially at night. Exposed to the sun in August, 1881, she had an attack of heat-exhaustion, followed by a second attack a week later. After this, her menstruation, always previously easy and regular, ceased for three months. During this time she was treated for malaria and her head became worse, which she attributed to the quinine. She became very nervous and

sleepless; lost all self-control; could not bear any noise of the children, the church-bell, or even her own voice. She became unable to do any work, and had extreme depression of spirits; attempts at suicide were repeatedly contemplated, but, though almost determined to end her life, she was deterred by her religious fears. These emotions were readily confessed to me and to her husband. In December, 1882, her menstruation became very profuse, and was continuous for three months. Since then it is not continuous, but is still very profuse.

Meantime, in October, 1881, by spells her sexual appetite, till then a matter of little moment, became immoderate. Day and night it was an exquisite physical and mental torment, and even led her to repeated self-abuse when it could not be gratified. This nymphomania and her head-symptoms were always worst at her menstrual period. Finally, she went voluntarily to an insane hospital in March, 1882, being utterly unfitted for her household duties and in constant dread of suicide, but soon returned home.

January 2, 1883. I saw her; head still as described, and she was almost desperate; uterus normal, except some erosion at os, and freely movable; clitoris and other generative organs normal. Her attacks of nymphomania were still frequent and severe, especially during menstruation. She was fast passing towards permanent insanity. She loathed herself for her abnormal sexual appetite; she had struggled against it, as well as against her suicidal intent, till she was ready to hail anything that gave the faintest hope of relief at any risk to life, for which she cared absolutely nothing. She had been under varied and excellent care, and every moral means and all promising drugs had been freely tried. I therefore proposed Tait's operation, to which she and her husband instantly assented.

4th. Operation; ether; antiseptic method (carbolic acid), with spray; bladder emptied; incision three inches in median line upward from pubes; layer of fat (she was well nourished) one inch thick, belly-wall two inches. Left ovary found without difficulty; its pedicle pierced by needle with eye in the point carrying a double carbolized silk ligature; ovary and Fallopian tube tied separately and ligatures cut short. One ovarian vein was varicose and as large as the little finger; ovary and tube both removed. Two pedunculated growths of the size of peas were attached to the ovary, one directly and another from the middle of a long foot-stalk attached at the two ends to the ovary and to the tissue between the ovary and tube. The right ovary was found with some little difficulty; as it was pulled out of the wound a small cyst burst. It was treated precisely as the left, and tube and ovaries removed. Both tubes and ovaries were intensely congested (her last menstruation was five days past); several small cysts existed in each.

Her recovery was uninterrupted. She had a little bilious vomiting, and retention of urine requiring the catheter, but no pain; and no medicine.

8th. A moderate vaginal hemorrhage began, which ceased four days later spontaneously.

9th, 11th, and 14th. The stitches were removed. Her highest temperature was 99.4°.

19th. Down-stairs.

23d. Went home. Since then I have seen her repeatedly, the last time in the spring of 1885. Her mental symptoms and head-troubles have gradually become better. For the first six months or more she was often despondent, but she gradually recovered her cheerfulness to a large extent, resumed her household occupations, and is perfectly well. The nymphomania ceased from the time of operation, save two very slight and short attacks. Coitus is rare, but is entirely normal, and is not followed by any tendency to her former deplorable condition.

Case III.—Uterine Myoma; Severe and Long-Continued Hemorrhage; Operation; Death.—Miss W., æt. 40, first menstruated at fourteen, always profusely. For the last seven or eight years much worse, the flow continuing ten to fourteen days. In May, 1884, she began to suffer from continuous hemorrhage, which has persisted till the present date, January 2, 1885. Occasional severe hemorrhages also occurred. She is very pale and anæmic, with waxy lips, and has lost much flesh and strength, especially of late. To-day I examined her under ether: uterus three inches in length, and movable; a myoma as large as the fist was discovered in the anterior wall and fundus. Hypodermic injections of Squibb's ergot, in f℥j doses every second day, were used, to which, later, was added f℥j of the fluid extract of ergot daily, with tonics and good diet.

January 29. Has passed the menstrual period without noticeable hemorrhage, and to-day, for the first time since last May (excepting two days), has dispensed with a napkin. From this date till April her menstruation ceased. In April and May she had a normal discharge. But in June the hemorrhage returned, and continued so profusely as to threaten life.

July 4, 1885. The hemorrhage having been checked for three days by the above means, I operated. The tumor, which had clearly increased in size, was immediately seen on uncovering the belly. Ether; antiseptic precautions, including the spray (carbolic acid); bladder emptied. The enlarged uterus was so much in the way that the ovaries could not be seized through the small incision first made in the linea alba, the ovaries not having been carried up with it, and it had to be

prolonged one inch above the umbilicus. The whole hand had to be introduced, the uterus lifted and pushed forcibly aside, and the ovaries were even then reached with the greatest difficulty and after several attempts. The ovary and tube on each side were removed, the pedicle being tied with stout carbolized silk, which was cut off short.

The left tube was attached to the ovary at the fimbriated extremity; two cysts, one filled with blood and one with serous fluid, existed in this ovary, the stroma of which was largely cirrhosed. One large (size of an English walnut) and one smaller serous cyst were found in the right ovary, and its stroma was atrophied and cirrhosed. All four cysts were ruptured during removal. About eight ounces of serum were found in the peritoneum.

5th. The wound was united with silver-wire sutures after careful cleansing of the peritoneal cavity (there was no bleeding), and then dressed with carbolized gauze. Symptoms of peritonitis began to develop, and in spite of all remedies progressed to a fatal issue on July 7. The temperature was 102° to 103° till shortly before death, when it rose to 106°.

Autopsy.—July 8. Recent lymph was found over a considerable portion of the belly-contents, with an ounce of pus in Douglas's cul-de-sac. No hemorrhage had occurred.

NOTES ON RECENT PROGRESS IN PHYSIOLOGY AND PATHOLOGY IN PARIS.

VULPIAN'S RECENT RESEARCHES ON THE PHYSIOLOGY OF THE BRAIN.

PROFESSOR VULPIAN, the well-known physiologist, has, in a series of communications to the Académie des Sciences, described a long course of experiments, and their results, which throw a little new light on that obscure question, the physiology of the brain. Pflüger's theory is generally admitted by physiologists. MM. Rosenthal and Marey are among the rare exceptions who believe that it is based on results which have not been clearly demonstrated. This theory admits that electric stimulus communicated to a nerve becomes more and more intense in proportion as it travels along the nerve from the stimulated area towards the periphery, therefore of necessity an electrical stimulus of unvarying intensity produces muscular contraction more and more exaggerated according to the increased distance of the stimulated area from the muscles. Another logical deduction from Pflüger's theory is, that a current which is too weak to provoke muscular contraction near the peripheral extremities would have this effect if the current communicated the nerve-stimulus to a point farther removed from the nerve-terminations.

M. Vulpian made the following experiment, which negatives Pflüger's theory. A dog was submitted to the effects of chloral until the reflex phenomena which have their origin in the medullary substance were entirely suppressed. The external popliteal nerve was then isolated at the upper part of the thigh, and a glass rod was passed under it without cutting it. The tibialis anticus was isolated in the same manner, and it was stimulated by a current from Du Bois-Reymond's apparatus. When the two coils were separated by a distance of five hundred and ten millimetres, the foot contracted. The external popliteal was stimulated by this same current, but no movement was provoked. The coils were then placed closer together by fifteen millimetres, at a distance of four hundred and ninety-five millimetres, and contraction took place. Other experiments made by M. Vulpian were equally adverse to the accuracy of Pflüger's theory.

Having obtained these data concerning the peripheral nerves, M. Vulpian extended his researches in order to ascertain if the same phenomena were repeated in the brain, and if the gray substance presented certain areas, some more easily stimulated than others, as is supposed by some physiologists who have studied the effect of electrical stimulus on the cerebral surface. When in a dog's brain those cortical regions which are admitted to be the motor centres for the facial muscles, for the fore and hind legs, are successively subjected to the influence of an electrical stimulus, it is observed that the first region enumerated is influenced by a weaker current than the second, and the second by a weaker than the third. The distances between the coils of a Chariat apparatus were respectively one hundred and eighty-five millimetres, one hundred and seventy-eight, and one hundred and seventy-five. As the experiment first described demonstrates that the strength of the current must be proportionally greater the farther the region stimulated is removed from the periphery, it is not logical to suppose that one cerebral region is more easily stimulated than another, but that it is a question of distance, and a certain proportion of stimulus is spent on the road (by resistance). This

second experiment is additional evidence that Pflüger's theory is fallacious. Its results, likewise, have a direct bearing on cerebral pathology which deserves serious attention. A stimulus communicated to regions of the gray cortical substance may be powerful enough to stimulate the nucleus of origin of the facial nerves and provoke facial movements, but not powerful enough, though actually in existence, to stimulate the nuclei of origin of the nerves of the limbs.

M. Vulpian, farther on in his researches, succeeded in establishing a fact that negatives many others hitherto admitted with regard to cerebral localization. Many experimentalists believe that certain motor and sensory centres are localized in certain given cerebral areas. Some clinical phenomena seem to support this doctrine, others to disagree with it. M. Vulpian's experiments indicate that the gray cortical substance is not excitable by the current in the areas known as special centres, but in the underlying white substance. He isolated electrical conductors by means of gutta-percha and then passed them along the gray substance, and was thus able to observe that an electrical current which was not strong enough to stimulate the gray substance provoked movement. He also ascertained that if the gray substance was congealed by means of methyl chloride, an electric stimulus provoked movements in those limbs of which the motor centres had been localized in the gray substance which had been destroyed by congelation. These two experiments indicate that the centres which had been localized in certain regions of the gray substance have no real existence. The real origin of the nerve-fibres is in the underlying white substance, and therefore the gray substance does not present isolated groups of cells affected to different functions. This peculiarity of structure, moreover, is entirely contrary to what is known of the intimate structure of the gray substance.

M. Vulpian has ascertained by means of his experiments that the brain is capable of receiving a stimulus only during a few seconds after death. Once only he observed in a dog's brain the stimulation-period extend to nearly one minute and a half after the cardiac movements were suddenly arrested by electrization. M. Vulpian affirms that in those cases where experimentalists have believed that stimulation of the cerebral motor regions has lasted longer, they have mistaken for cerebral stimulation contractions resulting from direct electrization (by direct or diffused currents) of the nerves and muscles near the brain. The contractions produced by faradization of the cerebral lobes a few minutes after death never take place in the limbs, but are always limited to the muscles of the face (especially the temporal muscle) and the muscles of the neck (the trapezius muscle included). M. Vulpian's assertions are in reference to experiments made after part of the cranium has been removed. The results of those made under other conditions cannot be considered valid. If the faradic current is not very intense, these contractions are always limited to the side faradized. If the left cerebral lobe be electrically stimulated, the contractions appear on the left half of the face and neck. If the current be sufficiently strong to provoke contractions on both the left and the right side, they are always more marked on the side which has been submitted to faradization. Direct stimulation of nerves and muscles by means of direct or diffused currents is followed by phenomena exactly similar to those obtained by the following experiments, in which stimulation does not enter into the question.

A few minutes after crural pulsation was arrested in a dog by faradization of the cardiac ventricles, the brain was quickly removed by cutting the spinal cord behind the medulla oblongata and cutting also the cranial nerves. After a few minutes had elapsed, the brain was carefully replaced in exactly its normal position. The electrodes of an apparatus of induction-currents were placed on the cerebral lobes. The points of these electrodes were at a distance of .005 of a millimetre from each other. A strong current was then passed, and the temporal muscles and the muscles of the side of the neck corresponding to the cerebral lobe electrified were electrified. When the posterior third of the cerebral lobe was faradized, the muscles of the neck especially contracted, but still more powerfully when the surface of the cerebellum was stimulated. These phenomena occurred about half an hour after cardiac contraction was arrested. When the electrodes penetrated the lobes, the contractions were more violent than when applied to the surface. Contractions also occurred when,

after the brain was removed, a moist sponge was placed on the medulla oblongata. When a faradic current was passed through the sponge, contractions of the temporal muscle or of the muscles of the neck took place on the side electrified, according to the areas which received stimulation. M. Vulpian has, by electrifying the surface of the wet sponge by a strong current, provoked contractions in the temporal muscle of the corresponding side forty-five and fifty minutes after circulation had ceased. It generally happens that these phenomena that are clearly observed twenty-five minutes after circulation has been arrested are not repeated thirty-five minutes afterwards.

These experiments have been made on dogs; but M. Vulpian does not believe that the period of cerebral stimulation after death in adult dogs differs greatly from that of other adult mammals, unless they are hibernating mammals and in a state of hibernation.

The cause of death influences but slightly the length of this period. In cases where death results from sudden arrest of the circulation, the stimulation-period after death is of the longest duration.

(To be continued.)

TRANSLATIONS.

Total Extirpation of the Carcinomatous Uterus.—Schultze, of Jena, contributes to the *Deutsche Medizinal Zeitung* (Nos. 1–4) a paper containing the report of twelve cases of extirpation of the uterus for cancer, three by abdominal section, all fatal, and nine by vagina, of which seven recovered. He insists upon the importance of early diagnosis, and reviews the history of the operation to prove that the earlier that patients suffering with carcinoma come under operative treatment the greater will be the proportion who, after several years have passed, will remain in good health. General practitioners are particularly enjoined in all cases of irregular hemorrhages from the genitalia of women, whether married or single, especially from the thirty-sixth year on, to make an exact local diagnosis of the cause of the bleeding, so that even an ulcerated carcinoma of the uterus shall be early recognized. The great majority of uterine cancers are still amenable to treatment when the ulceration has not progressed far. The possibility of the existence of cancer of the uterus makes even a leucorrhœa, at this time of life, occasionally of great significance.

With regard to the relative frequency of cases of uterine cancer, Schultze points out an error which has crept into a number of text-books. Glatter's statistics, based upon the 37,106 deaths occurring in Vienna of women over twenty years of age, showed that 937 died with uterine cancer (25 per thousand). The greatest proportion was noticed in the deaths occurring from 46 to 50 inclusive, 2763, of which 183 were of uterine cancer, or 66.2 per thousand. Gusserow (in Billroth's Handbuch der Frauenkrankheiten), in taking the cases by decades (instead of quinquennially) unconsciously doubled the death-rate. Schröder (Handbuch der Krankheiten der weiblichen Geschlechtsorgane) made a greater mistake in taking the figures of Glatter to represent the actual mortality from uterine cancer, whereas the original only referred to the proportionate mortality from this cause in the number of deaths from all causes. This error led Schröder to state that 6.62 per cent. of women at the age of 46 to 50 years die of uterine cancer, which is about eighteen times too great. The actual mortality at this age, according to the statistics above referred to, compared with the experience of life-insurance companies, shows that the proportionate mortality at this age among women is only about thirty-six per ten thousand.

Comparing the results of the abdominal and vaginal operations, Dr. Schultze says that, according to Hegar (1881), the mortality of Freund's operation was 71 per cent. (and it may be still greater, since operators do not always promptly report their fatal cases), and that of the vaginal total extirpation only 25 per cent. Sänger (1883) placed the mortality of 133 vaginal operations at 28.6 per cent., whereas Schmidt, continuing the statistics in 1885, collected 242 vaginal total extirpations, with only 64 deaths (26.3 per cent.).

Cases will occur in which total extirpation is indicated, but, on account of the size of the uterus, it can only be removed per abdomen. In such cases the peritoneal part of the operation should be performed as quickly as possible. The preliminary operation of cutting around the carcinoma per vaginam (as recommended by Rydygier)

not only increases the safety of the patient at the time, but also enables the operator to be sure that nothing of the carcinoma which can be removed remains in the vagina. If it be possible thus to free the cervix uteri from the vagina, the peritoneal section can be accelerated, and the danger of the Freund operation materially lessened.

In all cases a careful diagnosis as to the extent of the carcinoma should be made, under an anæsthetic. This is done by placing the index and middle fingers in the rectum, the thumb in the vagina, while the other hand is placed on the abdomen. If this examination show that the carcinoma of the vaginal portion reaches to the height of the cul-de-sac of Douglas, then, obviously, nothing remains but the radical operation of total extirpation.

In cases of isolated carcinoma of the corpus uteri, the amputation of the fundus of the uterus per abdomen, theoretically, would be the proper operation; yet statistics show the danger of this operation to be much greater than that of total extirpation. In cases of carcinoma of the fundus, therefore, when the uterus is small enough to be removed through the vagina, this operation should be preferred to removal by laparotomy; for the amputation of the fundus per abdomen shares with Freund's operation the danger of injury to the intestines, and also that of peritoneal infection by the cancer-juice from the section. This is avoided in the vaginal method of total extirpation. Any danger of infection of the peritoneum through the healthy cervix can also be excluded by efficient tamponade of the cervical canal. The supravaginal amputation of the carcinomatous corpus uteri by means of laparotomy would therefore be reserved for those cases only in which the uterus is too large to be removed through the vagina.

Dr. Schultze states that a vaginal amputation of the fundus has never been accomplished to his knowledge, but he considers it a possible operation in selected cases. The injury of the operation is still less if the anterior wall of the vagina is left intact and the cervix can be left in connection with the bladder. Should unexpected difficulties arise preventing the carrying out of the operation, it can be completed as one of total extirpation.

An operation for the removal of the carcinomatous uterus is based upon the possibility of the removal of the entire carcinoma, but the extent of the disease is not always easy to determine, and can only be decided by experiment. Most operators have uncompleted operations in their experience. The value of statistics depends upon a report of all cases, whether favorable or unfavorable.

Treatment of Lupus by Applications of Ice.—The slow course of lupus, as compared with that of tuberculosis of the interior organs, certainly bears some relation to the scanty appearance of bacilli existing in lupus new-formations, which in turn is dependent upon the colder temperature of the external skin, as it is well known that at a temperature of 30° C. the bacilli develop very sparingly, and at 28° C. no further development occurs.

Professor Gerhardt, of Berlin (*Berliner Klin. Wochenschr.*, No. 41, 1885), in view of this fact, attempted through refrigeration to check the growth of the bacilli, and consequently the further formation of lupus-tissue. He suspended an ice-bag from a frame directly over the patient so as to cover the whole or greater part of the surface of the lupus without pressure upon it, when the patient was lying upon his back. The average length of the ice-application was three hours twice daily.

In three cases of lupus of the nose, although the treatment could be applied for only a comparatively short time (two to four weeks), the result was very evident. The diseased areas became covered with a new skin, infiltration disappeared, and the skin was soft and smooth, though still a few nodules were present. In a fourth case of lupus, involving the whole left cheek, the region of the lower jaw, the ala of the nose, and the eyelid, after two months' treatment only one small tumor or nodule was left in the region of the lower jaw. In the other parts the skin was smooth, pale, and thin.

Whether the cure is permanent or not remains to be determined, as, according to the investigations of Schill and Fischer, the bacilli may retain their vitality for weeks in putrefying sputa; yet it is to be supposed that when exposed to such unfavorable vital conditions they are put at great disadvantage in the struggle with the vital processes going on in the cells surrounding them.—*Deutsche Medizinal Zeitung*, No. 2, 1886.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, FEBRUARY 6, 1886.

EDITORIAL.

ÆSCULAPIA VICTRIX.

IN the January number of the *Fortnightly Review*, Mr. Robert Morris writes entertainingly, under the above heading, of the origin and progress of medical education for women in Great Britain. His facts are almost altogether derived from English experience, although the status of female medical practitioners in this country is once or twice referred to.

The London Medical School for Women was started in 1874, largely through the energy and ability of Dr. F. E. Anstie, who was elected first dean, but who unhappily died from septicæmia contracted while making an autopsy before the school was opened. Among the lecturers have been the following: Messrs. Reeves, Rivington, Heaton, Berkeley Hill, and Critchett, Professor Shaefer, and Drs. Donkin, Sturges, Thomas King Chambers, Bastian, Cheadle, and Sankey. Probably no single school in London has a more brilliant teaching staff. Most of the above are also attached to other schools in the metropolis. Active work was begun on a capital of little more than five thousand dollars.

It was three years after the organization of the school before medical women could qualify before any of the licensing bodies, and it was not until 1878 that the authorities of London University voted to admit women to all the degrees. The vote by which this conclusion was reached is interesting, and apparently shows that doctors are more conservative than other classes of men of liberal education. The vote is as follows: in favor of granting the degrees were twenty-two graduates in medicine, thirty-three in science, twenty-eight in law, and one hundred and forty-eight in arts; the votes in opposition to granting examinations and degrees to women were cast by eighty-three graduates in medicine, four in science, nine in law, and thirty-six in arts.

Since the school was opened in 1874, one hundred and fifty students have been admitted, about one-third of whom have qualified for practice in Great Britain.

Regarding the chances of medical women for professional success, the writer in the *Fortnightly* takes, on the whole, a favorable view. In fact, he thinks "that a woman has rather a better chance than a man in starting as a doctor, for if she settle in a good provincial town she usually has no competitor of her own sex to fear, and, without buying a practice, she is pretty sure, even though she put forth no very extraordinary efforts, to earn about one thousand dollars a year after being in practice for two years."

In the United States the chances of success for the average female practitioner are probably a little more favorable.

The removal of certain conservative restrictions in a number of local, State, and national societies, which formerly prohibited female membership in such societies, is an evidence that in this country also the claims of medical women are becoming recognized by the profession. The recent appointments of female *internes* in some of the Paris hospitals, and of a woman as medical inspector of schools in that city, show that the daughters of Æsculapius have likewise obtained professional standing in France.

With a fair field and perhaps a little favor from the sterner sex, the path of the female practitioner should henceforth be, if not exactly and exclusively a path of roses, at least one in which the thorns are not too numerous and salient. It is evident that women have entered the profession to stay.

THE REDUCTION OF EXCESSIVE BODILY WEIGHT.

IN the method of Oertel, obesity is to be overcome by decided reduction in the fluid elements of the food, conjoined with systematized muscular exercise. From the accounts published regarding the "Terrain Kur," it is seen that not only is the total weight of the food reduced to about one-half, but the water is reduced to even a lower proportion. The constituents of the diet are also materially altered by reducing the carbohydrates and increasing the nitrogenous principles. For instance: a healthy man takes, on the average, about 130 grammes of albumen, 84 of fat, and 404 of carbohydrates; Oertel gives his patients 169 of albumen, 43 of fat, and 114 of carbohydrates. This system of treatment thus briefly indicated bears the endorsement of personal experience, Dr. Oertel having applied the teachings of Pettenkofer and Voit to the improvement of his personal health, comfort, and appearance. Although his method has been received with evident marks of favor by the medical press generally, we are glad to observe that the *London Medical Record* sounds a note of warning, on the ground that it does not seem to be based upon sound physiological principles. Even though conducted, as its author urges, under strict medical supervision, it is possible that serious strain may be put upon the organs of circulation and the kidneys, which under such circumstances are always in a more or less pathological state. The diminution of the fluids of the diet acts upon very nearly the same principle as the administration of concentrated saline solutions in cases of pleuritic effusion, as lately recommended by Dr. Hay, of Aberdeen,—the result aimed at in each case being to reduce the total volume of blood, and thus to stimulate the absorbent vessels to greater activity.

An essential part of the treatment of Oertel consists in requiring the patient to take a course of exercise in walking, first on a level ground, and then on gradually increasing gradients. This involves the selection of a site for the carrying on of the cure in a mountain region, and several establishments under medical care have been opened at Meran, Bozen, Arco, Baden-Baden, Abbagia, and elsewhere. Here the details as to diet and pedestrianism are carefully regulated by the medical attendant, and the reports which have been received of the results of the treatment have been highly favorable.

Perhaps the pure mountain air inhaled during the daily walks may have exerted no inconsiderable influence in improving the bodily vigor, but the restriction in eating and the limitation of alcoholic stimulants to the minimum, with the muscular work daily, are measures admirably calculated to reduce excessive corpulence, provided that due regard be had to the state of the kidneys and circulation. These recommendations might almost be summarized in the classical advice of Abernethy, "to live on sixpence a day and earn it," which many might learn to do with advantage.

While overfeeding finds its natural corrective in semi-starvation, and the results of indolent and luxurious habits may be overcome by temperance and physical exercise, it is evident that great care is required in making special and severe and sudden applications of this principle in a class of subjects whose powers of vital resistance are low, and who are often regarded as *opprobria* of both medicine and surgery.

PARVIN ON THE REMOVAL OF THE UTERINE APPENDAGES.

IN the course of the discussion upon the paper of Dr. Parish which appeared in our last issue, when it was read before the County Medical Society, Dr. Parvin admirably summed up the principal features of the subject in the following words:

"The great point in the whole matter is the necessity for sterilizing women. If it be right, as it certainly is, in given conditions to destroy

the very purpose of woman's sexual character and to render reproduction impossible, the question arises, What are those conditions? The gravity of the physical change in woman's nature cannot be too strongly presented. Notwithstanding all that has been said in regard to a woman's retaining sexual desire after the removal of her ovaries, she is no longer a woman so far as the essential design of her physical nature is concerned: her reproductive power is gone. There may be sexual enjoyment, but she has become one of Lord Bacon's barren virgins. She now is one with whom sexual intercourse occurs for pleasure, not with the hope of posterity. In this respect she is no longer a wife, but becomes a prostitute,—one for whom sexual intercourse is an end, not a means. So far as sex is concerned, she has become a neuter.

"Several indications for the operation have been presented, but I will refer to only one or two. The first of these is the presence of uterine myomata causing dangerous hemorrhage. When these tumors cause hemorrhage they are usually submucous. But a submucous tumor is in the process, usually, of becoming pedunculated, and it is possible that in some of the cases where removal of the uterine appendages has been done, a little patient waiting, with temporary means for moderating the hemorrhages, and one might have found the tumor pedunculated, when its removal through the vagina could have been effected.

"Again, we have to consider the mortality of the removal of the appendages for myomata. I doubt the propriety of taking Mr. Tait's statistics as our guide. The question is, How many will die when the operation is done by moderately skilled hands, or the average skill of those doing such operations? At the Copenhagen International Congress, Wiedow reported one hundred and forty-nine cases, with a mortality of ten per cent. Tissier more recently has collected one hundred and seventy-one cases, with a mortality of 14.16 per cent. In the latter's cases there were eleven in which the result sought by the operation was not attained. A most interesting case has recently been reported by Mr. Tait in the *British Medical Journal*, where removal of one ovary and a part of the tube failed to arrest the growth of the uterine tumor, as well as to stop the hemorrhages. Only the tube and ovary of one side were removed, he failing to find the other. Hysterectomy was done, and there was found to be congenital absence of the tube and ovary on one side. He explains the continuance of the hemorrhage and of the growth of the tumor by the fact that only a part of the tube was removed in his first operation.

"And here arises the question as to the organs it is essential to remove, a question that is answered differently by different authorities. Mr. Tait holds that the tubes are the essential organs, and in some cases has removed them alone, leaving the ovaries. On the other hand, Sir Spencer Wells would not remove the tubes unless they were diseased.

"I know of no statistics showing the mortality in moderate-sized uterine myomata; and it is in such cases removal of the uterine appendages has given the best results, for when the tumor is very large of course the mortality is greater, and the result finally not so certain. A comparison of such statistics, could they be had, with those of removal of the uterine appendages in regard of mortality, would be most valuable.

"A word as to diseased oviducts demanding removal. It is certainly remarkable that Mr. Tait has met with so many such cases, while Emmet has seen but two, and both of these got well without an operation. Dr. Emmet has told me that the greater prevalence of such serious disease of the tubes in Mr. Tait's practice is to be attributed to the greater frequency of gonorrhœa in the women there than in our country.

"I believe there is much to be learned as to the limitations of the operation, and it will probably be years before firm ground is furnished upon which all the profession can rest. Dr. Parish's contribution helps to the attainment of this end. I think most if not all of his conclusions can be accepted."

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

WHILE medical journals grow and multiply and prosper with you, a very different state of affairs obtains here. An attempt some ten years ago to float a new metropolitan medical journal ended in failure, and now a well-known if secondarily important member of the little group of

journals devoted to medicine is disappearing from vision in London. Forty years ago the *Medical Times and Gazette* was a vigorous periodical, remarkable for its scientific articles and its *esprit.* It possessed originality, and gave some long series of articles which afterwards appeared in book-form as "The Races of Man," by Knox, famous or infamous from his association with the Burke and Hare murders for anatomical purposes in Edinburgh. D'Arpentiny on "The Hand" appeared in a series about the same time. In the spring of 1862 a most valuable series of papers on "Physiognomical Diagnosis," from the pen of the late Professor Laycock, Professor of Practice of Physic in the University of Edinburgh, came out in the then flourishing *Medical Times and Gazette.* Marion Sims was severely handled by it for the conduction of his observations on sterility. It possessed a high tone, and was a keen stickler for medical ethics and proprieties. For long Sir Spencer Wells was its editor, a position he held when rescuing ovariotomy from the list of unjustifiable operations. Then Jonathan Hutchinson was one of its staff, and many a thoughtful, masterly article was the product of his pen. The late Dr. Silver was for years its guiding spirit. But somehow it lost its prominent position. The well-known medical publisher, Churchill, was its proprietor; and in it and the defunct *Medico-Chirurgical Review* he filled a conspicuous position in medical literature. But some years ago the *Medico-Chi.*, as it was termed, dwindled out of existence, and now the *Medical Times and Gazette* has followed its example. A certain spirit of Philistinism crept into both as death approached, and neither can be said to have died lamented—unless it is by those who took its pay. Under the cover of anonymity some ruthless and savage attacks were made on rising men by the *Medico-Chi.*, who did not either forget or forgive their assailant when they rose to be formidable. We may say "Peace to their ashes" in both instances.

For some months past it has been my intention to give some account of the discussion on glycosuria which came off at the annual meeting of the British Medical Association at Cardiff in July last. But so far I have waited in vain for an account of it in the Association's Journal, and inquiry elicited the fact that some of the speakers experienced a difficulty in putting into writing what they had said, or thought they had said, or wished they had said: anyhow, they had not made up their minds what to put on record. At last Dr. Pavy's introductory address has appeared in the *Lancet*, and it becomes possible to give some—if but a fragmentary—idea of what was said. Of course the medical world looks with the greatest interest to what Dr. Pavy had to say, he having been for long the leading authority on the subject of diabetes. As "the clinical aspect" alone came under consideration, the pathology of the disease and its relation to a high blood-pressure in the hepatic artery were not touched upon. He included classical diabetes mellitus, as well as those cases where sugar appears in the urine without any subjective phenomena, under the wide term "glycosuria."

The first matter he discussed was the age at which it may appear, his opinions being based on thirteen hundred and sixty cases from his private note-books. It seems no less than eight cases appeared in children under ten years of age. Another case, not included in his tables, occurred in an infant one year and three weeks old. "The infant had been rapidly wasting, had shown great greediness after fluids, and was passing an excessive quantity of urine, which saturated the articles worn and rendered them stiff on drying." The infant died exhausted a month later. Then he said, "As regards the family history, there are some interesting points to be noted. There can be no doubt the disease runs in families." He then gave a series of cases corroborative of this statement. Three sisters, over fifty years of age, consulted him,—one in 1873, one a year later, and an older sister (fifty-seven) in 1879. All three are still alive. Both their parents had consulted him for glycosuria some years previously. Of another family, two brothers and a sister were diabetic. In another instance, two members of the family died young with it, and another member, aged thirty-two, was suffering therefrom. This last "still continues in good health." So, after all, diabetes is not so deadly as it is usually supposed to be by those comparatively unfamiliar with it. In another family the grandmother and mother died of diabetes, and four out of five girls had their urine laden with sugar. One diabetic had three sons by various mothers, all of whom died with diabetes. He then went on to say, "I think there is every reason to believe that it is distinctly more common among members of the Jewish race than among others,"—a fact which goes to corroborate the view of the relations of glycosuria to mental exercise.

As to its mode of onset, he divided those cases where it came on gradually and insidiously from those where it occurred quite suddenly. In many cases, no doubt, a glycosuric condition had existed for a considerable period of time before its presence was detected. This he held proved by the fact that trousers which had long lain by were found to have splashes of urine leaving a white, sugary stain behind,—a stain not easily removed by brushing. It is in elderly persons especially that these stains occur. On the contrary, the attack in some cases was sudden and abrupt. In such cases some shock to the nervous system usually stood as an exciting cause.

"Then as to duration. This varies within very wide limits. It may go on for years without seriously impairing the patient's general

health, or it may terminate very speedily in death." In one case the disease ran its course in four days. In another the diabetes ended in a carbuncle over the parotid gland, running a course of a few weeks. Those cases where the condition goes on for years ("the patient meanwhile enjoying a fair state of health") are most common in elderly persons, though not confined to them. In one case glycosuria had existed in a lady for over twenty years without any impairment of her health. Such a case, he said, was not very unusual. Even in young people the case is not necessarily of short duration. A young lady whose mother died diabetic commenced to pass sugar in 1877. At the present time she voids a considerable quantity of sugar, though "there is nothing in her appearance which would lead one to suppose that she had anything the matter with her." She had married and borne children. He continued: "Although diabetes, when once developed, generally persists, cases occur where it has disappeared. I have from time to time met with these cases in my practice. I do not allude to mere control of the disease under dietetic management, but a complete eradication." One such case he related where in 1881 the patient was undoubtedly diabetic and in 1884 had no trace of it remaining. Sometimes glycosuria is but "a passing condition." He stated that diabetes insipidus and diabetes mellitus may occur in the same individual, and one may disappear, leaving the other behind. Or the one may precede the other, both disappearing ultimately.

He declined to discuss the causation of diabetes, as that involved its pathology. In some cases hydrosis of one-half of the body was found with glycosuria. A hypertrophic state of the liver was found as a concomitant of diabetes in a number of instances. Then he had seen it along with "abnormal conditions of the nervous system." Especially did he think it was found with locomotor ataxia. Sometimes one precedes the other; sometimes they appear simultaneously. There may be disorder of sensation. Then he also thought it linked with exophthalmic goitre. He then expressed his disbelief in "acetonæmia;" and as to the "coma," he had described it long before Küssmaul. Coma, he held, was apt to be induced by any fatigue. It is preceded by a curious breathlessness, which is followed by drowsiness. He did not think it caused by fatty emboli. Albumen may appear in the urine and go on for years. When present in small amount he attached no significance to it. "Other cases, however, exist which pass on to well-marked Bright's disease; and it is to be noticed that generally, as this condition becomes established, the diabetes has a tendency to subside."

Such, then, were the conclusions Dr. Pavy had drawn from his own experience.

The views expressed by the writer were corroborative of the wide range of maladies embraced by the comprehensive term glycosuria. There were, of course, the cases of classical diabetes mellitus, kept at bay for a time by a rigid dietary, but going on, as a rule, from bad to worse. Also those of sudden origin arising in some mental perturbation, usually of an acute character. From the causal relations of acute diabetes we could reason upon the relations of the more chronic form to long, severe mental toil, strain, or worry. It would appear that in many cases there is mere glycosuria, which deepens and deepens until distinct diabetes, including the uncomfortable subjective phenomena, is developed. If in these cases the mental factor can be put in abeyance, the physical condition can be brought to a stand-still. When, however, this mental factor is disregarded, the case progresses steadily in a downward direction. The liver is perturbed in many of its functions by mental operations, and as to its glycogenic function it suffers as certainly as it does in the metabolism of albuminoids, about which there is not much difference of opinion. This cessation from mental toil is being recognized as a very important matter in the treatment of glycosuria, both preventive and palliative. Then there are persons who find themselves diabetic, who under a suitable regimen remain simply glycosuric, but who are subject to "diabetic storms" on any worry or trouble further upsetting them. Then there is acute diabetes which gradually subsides, to be wakened into life again on any like exciting cause in the future. One old lady known to me has one of these "diabetic storms" set up by an ordinary cold. She goes to bed, rapidly emaciates, with thirst and saccharine urine, but after several weeks loses her symptoms and regains her wonted and ordinary health. Gouty persons, and especially corpulent gouty persons, are very subject to glycosuria, sometimes giving rise to diabetic symptoms. When sugar appears steadily in the urine of an old gouty subject, who at the same time begins to lose flesh, the prognosis is very gloomy. At other times and under other circumstances a saccharine condition of the urine takes the place of gouty symptoms, sooner or later the glycosuria disappearing with a return of the wonted gouty symptoms. The great difficulty in cases of glycosuria is not so much to discover evidences of the presence of sugar in the urine as to interpret correctly its significance when found. As long as there is no wasting there is little ground for anxiety, it not yet having been proved that the kidneys suffer from the passage of sugar through them. But when wasting is developed, then the system is certainly suffering from the waste of its grape-sugar. So long as there is no emaciation, the condition of glycosuria is comparatively unimportant. Indeed, many corpulent persons of middle age pass sugar continuously for years,

—sometimes more, sometimes less. Here it would seem almost a sort of "waste-pipe" affair,—a drain of the surplus grape-sugar not required by the system, and without which the corpulent person would become obese and unwieldy.

The extent to which the diet must be regulated in each case depends upon the individual circumstances and requirements. One person may find it necessary to abstain from ordinary bread, while another requires merely to avoid sweets. No one with any experience of diabetic thirst, with its unquenchable persistency, would willingly increase it or add to it. But in the absence of it (and other diabetic symptoms) it is very questionable how far harm rather than good is the outcome of a strict anti-diabetic regimen. Indeed, many glycosuric persons are of opinion that they have endured more from the regimen than from the malady for whose relief it has been adopted. Each case must rest, as to diagnosis, prognosis, and treatment, upon its own merits,—one thing being certain, that all cases of glycosuria are *not* diabetes mellitus.

* * * * *

What were the views of the other medical men who took part in this discussion must be recorded by some other pen. A decade has elapsed since Dr. H. C. Wood, then its editor, prevailed upon the writer to become the London correspondent of the *Philadelphia Medical Times*. Part of his instructions were to describe that inner life of the medical world in Great Britain which is a *terra incognita* to the roving correspondent; and this he has done from time to time, and not without incurring a certain amount of ill will and animosity in certain quarters. On the other hand, the manner in which his letters and their contents have been received in the Western Hemisphere was very gratifying to him. A man must be a colorless human chameleon who cannot rouse a feeling of hostility in some breasts; and such is not the writer's aim or ambition. He believes sundry desirable matters at home have owed some portion of their ultimate success to the outspoken utterances which have appeared in these letters. There are sundry other matters in the parturient stage to which he could have liked to lend a little obstetrical aid, such as it is in his power to offer. But a time comes when a correspondent must lay down his pen, and that time has arrived in this case. There is no longer the leisure which permitted of this correspondence being an agreeable pastime. As years advance, our interests are diverted into new channels. The advocacy of Dietetics in the Treatment of Disease is the absorbing topic with the writer at the present time. To him, indeed, it is the great therapeutic matter of the day, and he feels in duty bound to lend it what aid he can. Of the necessity of some systematic teaching of dietetics in a course of medical education no one can entertain a doubt. It is surely as desirable that a medical man be taught how to feed a patient acutely ill as how to prescribe for him. If it be a pyrexia, surely it is as desirable to maintain the strength, and call as little as possible upon the body-reserves, as it is to keep down the body-temperature by antipyretics. To prevent exhaustion both matters must receive attention. Every sick person is more or less a dyspeptic, and dyspepsia requires appropriate and suitable food. Many dyspeptics can alone perform their daily toil by a watchful attention to their food and food-requirements. The writer believes his labors have not been without influence in advancing our acquaintance with the means of increasing the energy of the cardiac contractions,—that our knowledge of the means of stimulating the respiratory centres owes something to his observations and experiments. He hopes to do something towards a more intimate familiarity with the kinds of food required by different morbid conditions, and to demonstrate that it is within our power to improve the action of the liver, when impaired, by reducing the demands upon it to the minimum of the body-needs, while raising its tone by certain remedial agents. Consequently he must bring to a close a labor which has been a labor of love, and say "good-by" to his many readers. When his correspondence began, the *Philadelphia Medical Times* was a lusty infant: now it is a stalwart youth, giving promise of enduring manhood. It has his good wishes for it in the future, as it has had them in the past.

J. Milner Fothergill, M.D.

NEW YORK.

OUR community has read and heard a great deal about hydrophobia lately, particularly since the Newark children were sent to Pasteur for inoculation. There has been some talk of establishing a Hydrophobia Institute here for the purpose of carrying out the new treatment. As to the value of Pasteur's method and the desirability of establishing an institute, opinions differ. This is but natural, for the question is a complex one, and perhaps with some there are influences brought to bear which would render their judgment not altogether impartial. If one should base his judgment on newspaper accounts, he might suppose New Yorkers were lovers of sensationalism; but when it comes to acting they are practical, and before putting their hands into their pockets they generally inquire, *Cui bono?* So, with regard to founding a Hydrophobia Institute, they ask, first, is it true that Pasteur has discovered a preventive of hydrophobia? Second, granting that it is true, is his method practicable and without danger? Personal interest may lead some to desire the founding of such an institute. Probably there are some physicians and members of the

laity who would like to see such an institution established, if for no other reason than that it would be a novelty and serve to bring the medical profession into prominence. Others, on the contrary, oppose it upon this very ground, believing that, if it should finally be proved that the alleged discovery has no foundation, it will bring discredit upon medical and scientific investigation in general, and upon special investigation as to preventive inoculation against disease in particular. There can be no overlooking the fact that inoculation against smallpox has been abandoned, and there certainly will be far less opportunity for establishing the efficacy of such treatment to prevent the development of hydrophobia.

Hydrophobia occurs rarely even in the dog. The dog may not bite a human being. A large majority of persons bitten by a really mad dog do not have hydrophobia. A number of months and even of years may pass before there occurs any active manifestation of the poison in the person bitten. It is not known, should the subject survive it, that one attack would afford protection against another in case the person should be bitten again. Moreover, there is a possibility that the virus employed against the development of hydrophobia may itself prove injurious, or even dangerous. These facts cause them to hesitate about going to the expense of building a special institution for the treatment of hydrophobia. But the numerous newspaper interviews with men who are said to have had special opportunities for learning all about Pasteur's methods, and the sending of the Newark patients to Paris for inoculation at the hands of the great Pasteur himself, have created a decided sensation, and it is not impossible that some of our people of wealth may be influenced to endow such a hospital. If they would do so, with the proviso that if the institution did not fulfil the object for which it was built the funds or the completed building should go to the Academy of Medicine, the undertaking doubtless would receive the approval of the medical profession of New York. As to the objection against founding an institution in this country that all patients could be sent to Paris for treatment (as Pasteur has suggested), it would not be entertained for a moment if there were no uncertainties about the diagnosis, or if full confidence were put in the method adopted by Pasteur.

The daily press shows quite a fondness for publishing reports of some rare and extremely wonderful operation, like trephining the skull or amputating a leg, performed by Professor A. or the great Dr. B. We know that one of the rules of ethics by which the medical profession is presumed to be governed is directed against seeking unseemly publicity or advertisement. But the ranks of the profession are overcrowded, and overcrowding means competition and rivalry. Consequently interviews with physicians, both young and old, continue to be easily obtained. For the same reason, there are many who would be willing to have wealthy people or the government found institutions which would pay them a salary for their services and at the same time give them publicity. There can be no harm if one who has specially fitted himself for a certain line of work or investigation desires employment in that direction, if it be of benefit to man; but due regard should be had for the rights of less enterprising members of the profession, who are not, however, less well qualified for the place.

We hear in this city comparatively little about the International Medical Congress. The majority of the profession, of course, have not a national reputation, and cannot expect to take much part in the meeting. Many of the more noted are "New Code" or "No Code" advocates, and would not expect to receive a very warm welcome under the existing condition of things, and others belong among those who are opposed to the action of the New Orleans meeting and of the Committee there appointed. They say, however, that if the original state of things were re-established they would do all in their power for the Congress; and if this course were adopted, probably our leading physicians would feel a special responsibility resting upon them to do all they could to make the Congress a success.

It is announced that Dr. H. B. Sands has resigned his surgical professorship in the College of Physicians and Surgeons, and that a concourse will be held at which Drs. W. T. Bull, W. S. Halsted, and R. J. Hall will take part, each delivering about ten lectures, after which the Faculty will decide which one shall fill the vacant chair. It is doubtful, however, whether Dr. Halsted's health will permit of his competing for the place.

At the annual meeting of the New York County Medical Association, January 18, 1886, Dr. Charles A. Leale was re-elected President, and Dr. P. Brynberg Porter Secretary. Dr. John F. Shrady was elected Vice-President.

It having been charged that our Board of Health was extravagant, as a consequence the amount appropriated to this department by the Committee on Apportionment has been cut down for this year. Extravagance existed in fact, and the medical members of the Board did not do what they could to prevent it. They certainly deserve censure: still, the value of their public services is undeniable: but it is a difficult task to bring the average politician to see the necessity of spending much money for so intangible a thing as the "public health."

Nearly a hundred papers have been prepared for presentation at the meeting of the State Medical Society, to be held February 2, 3, and 4, and if all shall be read there certainly will be no time for the discussion of

medical politics. The prospects are that the question of a Medical Licensing Board will not again be discussed before the Society, but it may again be brought before the Legislature during the winter. Mr. Lawson Tait, of Birmingham, England, will read a paper "On Methods of Diagnosis." The meeting promises to be an unusually interesting one from a scientific point of view.

Our medical colleges are all being well attended this session. The College of Physicians and Surgeons have not yet begun the foundation of their new college building. The graduating class at the Bellevue Hospital College will receive a course of lessons in histology and pathology free at the Carnegie Laboratory. Dr. Biggs, of the laboratory, is on a visit to Europe to make special investigations relating to bacteriology, and during his absence will visit the laboratories of Pasteur and Koch.

The Post-graduate Medical School deny the report that they do not admit women physicians to their course.

Neu-Yorker Medizinische Presse is the name of a German monthly, of which two numbers have been published. Dr. George W. Rachel is the editor. New York has a large German population, and many German-speaking or German-reading physicians, and this journal meets a long-felt want. Dr. Wallace Wood has brought out a journal called the *Journal of Reconstructives, Dietetics, and Alimentation.*

J. D. Bryant, M.D., has been reappointed Surgeon-General of the State.

Dr. C. L. Dana has been appointed visiting physician to Bellevue Hospital.

Prof. Austin Flint will deliver the Address in Medicine at the next meeting of the British Medical Association.

The Alumni Association of the University of the City of New York held its annual dinner at Delmonico's, January 14. Many had not ten dollars to spare, and consequently were not present; but those who went enjoyed themselves profoundly.

Now and then a case of smallpox is reported to the Board of Health, but all fear of an epidemic seems to have subsided. During the week ending January 12, one hundred and two cases of diphtheria were reported, of which forty proved fatal.

At the Orthopædic Society, January 4, Virgil Gibney, M.D., presiding, Dr. Newton M. Shaffer presented an improved lateral extension shoe for talipes with which he had corrected some of the severest cases of the deformity known as equino-varus, the patient being able to go about during the treatment. He also presented an improved knee-splint, and Dr. M. Josiah Roberts presented an improved hip-splint. At the same meeting Dr. Le Roy Hubbard read a paper on excision for chronic disease of the shoulder, and Dr. Yale presented an interesting specimen illustrating the lesions of acute osteomyelitis of the hip-joint.

At the County Medical Association, January 18, Dr. Lawrence J. McNamara read a paper entitled "A Contribution to the Etiology of Tumors," in which he expressed views adversely to the bacterial origin of cancer, and, incidentally, to the evolution theory, that an animal low in the scale of life may beget one higher. Dr. Janeway sent specimens illustrating epithelioma of the anterior wall of the œsophagus, causing paralysis of both recurrent laryngeal nerves by pressure.

At the meeting of the Section in Practice of Medicine at the New York Academy of Medicine, January 20, Dr. G. L. Peabody read a paper on "The Size of the Heart in Chronic Diffuse Nephritis," and a general discussion took place on the question "Are the Antipyretic Measures at Present Employed in Acute Disease Useful and Safe?" In his paper, Dr. Peabody showed that cardiac hypertrophy was less common in chronic diffuse nephritis than was generally supposed, and that the common clinical teaching that the presence or absence of hypertrophy of the left ventricle would enable the observer to diagnosticate the presence or absence of chronic Bright's disease had no substantial basis.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting held at the Hall of the College of Physicians, Philadelphia, December 9, 1885, Dr. R. J. Levis, President of the Society, in the chair, a paper was read by Dr. James C. Wilson, entitled

THE CLIMATIC TREATMENT OF PULMONARY CONSUMPTION.

(See page 232.) This was followed by a paper by Dr. S. S. Cohen on

ARTIFICIAL CLIMATIC EFFECTS FOR "STAY-AT-HOMES."

(See page 339.)

DISCUSSION.

Dr. J. Solis Cohen: I think that we can all agree with most of the points mentioned by Dr. Wilson. There is great difficulty in selecting climates for those who are able to go away, and there is great difficulty in selecting the cases. My own opinion is that the cases which should be sent away, taking it for granted that those only are sent who can afford it, are those who are constantly "catching cold" from changes in the weather. They are to be sent away to avoid these changes. The best plan in selecting a climate appears to be that of finding out under what condi-

tions the patient is in the best health at home, and then to send him to a place where similar conditions are most constant.

Another important point, fully as important as the change of climate, is that the patient go to a place where he can obtain plenty of good food. The only hope of restoration in this, as in other chronic diseases, is from due nutrition. Medicinal and other treatment must be subordinate thereto. The secondary matters of avoiding places where there is overcrowding of sick people, of providing due occupation, amusement, etc., must also be considered in selecting the place of resort.

I should like to call attention again to a place already mentioned by the writer of the first paper. Lakewood is located some fifty-four miles from Philadelphia, in the midst of several thousand acres of pine forest, and here nearly all the benefit to be derived from such a climate can be obtained. In the winter-time, of course, it is necessary to wear shawls and wraps; but patients can often go out sleighing, and may almost dispense with the shawls and wraps when they reach the roads through the pine woods. There is a large hotel provided with sun-parlors, where patients may sit in the sun and take exercise in inclement weather. The patient can be readily visited by his friends, and even may come home from time to time for a day or two, if necessary, for business purposes. There are better accommodations for patients in moderate circumstances than at most places farther south, as the access to the New York markets is so easy that good food is readily procurable. If the physician paid more attention to these places near at home, there would be less necessity for sending patients to Aiken, Mexico, Colorado, Florida, California, and so on.

The idea that a patient with phthisis cannot in the winter-time subsist well in a cold climate has been found to be a mistake in many instances. This is a point to which attention is now being drawn. There are many who get along very well in Colorado, as they used to do so in Minnesota, and as they do in the Adirondack region. A patient who does well in cold, dry weather at home can go to such a locality and breathe fresh air, can take exercise in the open air, and will inspire and expire more deeply than at home, and thus be much benefited.

There is one other important point spoken of by Dr. Wilson, and that is that, when a patient finds a climate which agrees with him, he should make his home there. I have had several cases illustrating the value of this advice.

That the inhalation of compressed air and the use of antiseptic inhalations do a great deal of good I am convinced from an experience of many years. There are frequently cases in which we are unable to put our finger on any particular spot of pulmonary disease, and yet we are certain that respiration is not being carried on as it should be. There are probably certain unused areas of respiratory surface. In such cases the advantage of compressed air is soon apparent. Air is admitted to the lungs with more than the ordinary force. A little more force than that of ordinary voluntary respiration is all that is necessary. If too much force is used, there will be over-distention, and thus more harm than good will be done. Under the increased pressure the air passes into the unused portions of lung, sanguification is rendered more perfect, appetite is increased, and nutrition is improved. Antiseptic inhalations are not required in such cases. In a later stage, where there are a few crepitant or subcrepitant *râles*, without marked dulness on percussion, compressed air is also of service. Not only does it use the unused portion, but it exercises the sound portion of the lung and helps to clear out those accumulated products which are present, thus proving a better expectorant than anything that could be put into the stomach. By taking an inhalation just before going to bed, many a patient is enabled to clear out his chest and thus pass a comfortable night without the necessity for anodynes. At this stage, or later, when the parts are more or less sodden from retention of these materials, and when more or less decomposition is taking place, terebene, eucalyptol, creasote, and the other antiseptics may be used with advantage. It is not going to do a great deal of good if you simply give temporary inhalations of ten or fifteen minutes' duration. The patient should wear one of these zinc respirators all night. Their sieve-like construction enables the patient to breathe without being oppressed as in some other forms of respirator. There are other ways of conducting continuous inhalation of balsamic substances. A plan that I have often adopted, particularly with clergymen and other students, is to direct that a vessel filled with water be kept constantly before the fire in the study or sitting-room, and that a piece of rosin be thrown into the vessel from time to time. Another plan is to have some young pines growing in pots in the sitting-room. In this way the effects produced by residence in piny regions may be imitated, sometimes sufficiently to be nearly as efficacious.

There is a good deal to be done in the same line without apparatus. Prolonged inspirations, five to ten at a time, through a tube passing through the window-frame into the open air, is often very beneficial, especially on awaking from sleep. This plan may be repeated several times during the day with great advantage. Air enters the lungs under respiratory pressure, acting as does compressed air released from an apparatus.

I recall at this moment a marked illustration of the benefits of compressed air. Some

twelve years ago, a gentleman was brought from a distant city who with difficulty walked with assistance from the car to my door. He was placed on inhalations of compressed air, and in two weeks was so much improved that he was able to return to his home with an apparatus, which he used systematically. That gentleman was probably further advanced in phthisis than any patient that I have seen apparently recover. He is still living. I have had other similar but less striking cases. The best results have ensued where the patient has procured an apparatus for his own use at home, so that the inhalations could be taken systematically several times a day for prolonged periods. This is far better than intermittent inhalations in the office of the physician. And it is for this reason that efforts to simplify and cheapen the apparatus for pneumatic treatment of pulmonary diseases, rather than to complicate it and increase the cost, will be of benefit to the profession and to the community.

Dr. J. M. Keating: This is a subject in which I am much interested as a physician, having sent patients to many parts of the world, to Egypt, Cuba, Florida, etc., having accompanied them on some occasions, and once as a patient myself, as a convalescent from severe illness. Although the attempt at scientific precision in the analysis and classification of climate is most laudable, there are other matters to be taken into consideration, not less important, to which little attention seems to be given.

In the first place, it seems to me that the proper climate for a consumptive is an *equable* one. By that I mean an absence of sudden changes of temperature. I would go so far as even to include in this marked differences between day and night. This statement being accepted, the mean average temperature of the climate we select, whether it is to be cold or warm, depends on the patient; that is, sex, previous occupation, tastes, character of the disease, and the stage of the disease. There are some people who cannot bear a cold climate: this is especially so with delicate women, aged people, and of course those with advanced disease. Then, again, we should choose a place where there is much sunshine and a soil capable of readily absorbing superfluous moisture, and consequently free from malaria. I believe that there is very little specific effect to be derived from atmosphere except from its purity, freedom from dampness, and possibly in some cases the balsamic vapors it contains. Good food and abundance of it is just as important as pure air. Elderly men and delicate women do far better in a warm climate, because they can live continuously in the open air. It is on this account that sea-voyages are so useful in such cases. But young men in the earlier stages of phthisis or with an obstinate bronchitis should be sent to a section of country where they are obliged to live in the open air, but where a large amount of exercise is encouraged by a bracing atmosphere.

As I have said, it is necessary to know about the place to which we are sending our patients. You may say, "Go to Florida;" but there are more climates in Florida than in Pennsylvania. The patient may go to Jacksonville, and yet for pulmonary troubles this is certainly a treacherous place. There are here many very sudden changes, from intense heat to frost, severe storms, with cold and damp northeasters. St. Augustine is worse. Here, in addition to the above, there is a dust of coquina, or pulverized shells. The hotels are most comfortable; that is, for those who can afford to pay enormous prices. If your patient is not wealthy, he or she had far better stay at home. If you have decided that fresh air and sunshine are imperatively demanded, and the cold weather and sudden changes at home preclude any arrangements by which the said ends can be so supplied, and the patient is wealthy, there are many places near at hand to which he can go. There is Aiken, and Thomasville in Georgia, with delightful hotels, and many other places in the vicinity presenting the same characteristics. If your patient wishes to avoid any frost, you are safe in sending him to Enterprise, Florida; or, keeping away from the river and continuing down the spine of the peninsula, with the same sandy soil and pine forests we strike Altamonte, Winter Park, and Orlando, in Orange County, Florida.

I am satisfied that very ill cases with unfavorable prognoses should remain by all means at home. I have witnessed too many sad scenes, and have met with too many unfortunates who sought improvement and relief without the least prospect of amelioration, and who found nothing but expense, discomfort, bad food, exposure, and homesickness, to repay them for efforts which in the long run shortened their days. When you send very ill patients away, send them as near home as possible.

It is interesting to see that local treatment of pulmonary diseases is engaging so much attention, and from Dr. Cohen's paper we gain much information most useful to us as active practitioners. The largest number by far of our consumptives cannot get away: we have to treat them in our hospitals or in their homes. We have apparatus which can be readily used to inhale medicated air by the patient, and, with nutritious diet, equable temperature, pure air in abundance, and moderate exercise, we can accomplish a great deal for those who cannot afford the great expense of travel.

I believe that, so far as altitude is concerned in the treatment of phthisis, the tendency to overrate its importance is not so marked as in the past.

Dr. Edward T. Bruen: I have been much interested in both of the papers of this evening. The first paper touches upon a phase of the subject of the treatment of phthisis by climate which I have considered to a certain extent. My thoughts have been in the direction of obtaining some solid basis for advice to patients as to change of climates. The minor points to which reference has been made are to be considered; but I think that one of the main conditions that we are to look for in a climate is purity of air. The popular habit for many years has been to send patients to pine-regions, and these localities are known to furnish continuous supplies of ozone. With reference to purity of atmosphere as being a chief consideration, I may say that I have recently read a pamphlet by Schreiber, of Vienna, who gives the following facts: In Iceland, 65° north, where the coldest temperature reached is —28°, and the highest +56°, and the mean +40°; in Madras, in the torrid zone, in latitude 13° north, where the coldest temperature is +77°, the hottest +88°, and the mean +81°; and at a point in the temperate zone in latitude 51° north, where the coldest temperature is +3°, the hottest +69°, and the annual mean +35°,—in each of these localities there is freedom from consumption: the argument being that in each of these localities we have other conditions than the atmospheric influences operating.

It has been noticed that in high altitudes phthisis has increased when manufacturing establishments have been introduced. On the other hand, it has been found that the proportion of phthisis decreased in low meadow-lands where the inhabitants lived an out-of-door life. If pure air be a desideratum for this class of cases, we can obtain this pure air near at home. I have had reason to form a very favorable estimate of the value of Lakewood and the surrounding region. In some of the neighboring counties of Pennsylvania we can obtain this purity of air as well as in distant localities. Some fifteen years ago, McCormack, an English physician, wrote on the importance of rebreathed air as a factor in the development of phthisis, and advised that people sleep with open windows and with a free circulation of pure air in the chambers of those suffering under pulmonary diseases. We can thus see that this subject has for a considerable time occupied medical thought. With pure air we must have a maximum amount of sunshine, and a warm or cool climate, as is most agreeable to the constitutional peculiarities of individuals.

Although I have not used the methods of Dr. S. S. Cohen, I have always followed the principle involved, and have employed light gymnastics to stimulate the respiratory muscles and thus secure as perfect inflation of the chest as possible.

It goes without saying that in a wasting disease such as phthisis the diet question is of great importance, and must be considered in connection with any climate.

In reference to the Colorado climate, while it possesses many advantages, I have learned by correspondence with patients that sudden and great changes in the thermometer often occur. In one case the temperature ranged in one day from zero, Fahrenheit, to plus seventy degrees. One other point: the water of a locality should receive considerable attention; and this is an objection to Colorado and New Mexico, where the water is largely limestone and not very pure. Dr. J. S. Cohen's mode of climatic selection seems very practical.

Dr. L. F. Flick: I have been much interested in the discussion of this evening, because at one time I was myself sent in search of a healthy climate. I think it is a question whether climate has as much to do with the benefit derived as the change of habits of life. My experience has been that the individual who takes plenty of out-door exercise improves, while he who expects to get benefit simply from the climate is doomed to disappointment.

In my own case I attribute my improvement to work in the open air with forced alimentation. I sometimes took as high as six to eight quarts of milk a day, and in sixteen months I gained fifty pounds.

I think that too much stress has been laid on climate. I think that in Pennsylvania we can get as much benefit as anywhere in the country. The Lehigh Valley and the Alleghany Mountains furnish as good climates as can be found anywhere. In certain places in these regions consumption is never heard of. A matter that has struck me forcibly is that where consumption is not heard of malarial troubles are likewise absent. By sending patients to these resorts near home they are saved much unnecessary expense.

A point which Dr. Bruen has called attention to in connection with certain climates spoken of by him applies equally well to the Western climates: namely, the great amount of dust. This holds good especially in regard to Colorado, New Mexico, and Arizona. Another point in reference to these climates is that, while the temperature may be equable, there are great variations between day and night. In such regions patients should not go out except while the sun is shining.

Dr. William M. Welch: I rise simply to ask Dr. Cohen if he has had any experience in the use of rarefied air. I have somewhere seen a description of an apparatus intended to contain rarefied air for therapeutical purposes. I recollect that Dr. Dennison, in his work on "Colorado as a Health-Resort," speaks very positively of the beneficial effects of that climate on asthmatics. The patient does not have to live in that climate any length of time before benefit is obtained, but

it comes at once. As one of the peculiarities of the climate of Colorado is great rarefaction of the atmosphere, it seems reasonable to suppose that rarefied air, artificially produced, should be of service in the paroxysms of asthma.

Dr. Neff: The instrument referred to is probably that which has been used in Brooklyn by Dr. H. F. Williams. The patient is surrounded with an apparatus in which the air can be condensed or rarefied. The process is termed pneumatic differentiation. I notice in reading the reports of cases treated in this way that hæmoptysis is not considered a contra-indication for this plan of treatment, and even in threatened hemorrhage this treatment has been used. In the neighborhood of a hundred cases have been reported as treated by this method, with very favorable results, by Dr. H. F. Williams,* of Brooklyn, Dr. A. S. Houghton,† of Chicago, and Drs. De Watteville and Seigel. Several of these cases were under the observation of the late Dr. Armor, of Brooklyn, and Dr. Alfred Loomis, of New York. It seems to me that the use of compressed air would be contra-indicated where there is any tendency to bleeding.

Dr. J. Solis Cohen: I would say, in reply to Dr. Welch's query, that I have had considerable experience with the use of rarefied air. It offers beyond question the best method of treatment in recent cases of asthma and in asthma in young persons. Expiration into rarefied air is better than inhalation, in most instances. Dr. Neff is correct in thinking that the breathing of compressed air increases the tendency to hemorrhage. The pressure on the blood-vessels is increased, and, if there is a tendency to bleeding, this favors it.

Dr. Frank Woodbury: The remarks of the lecturer and of Dr. Cohen with reference to the sending of invalids to health-resorts near at home struck me as being very pertinent. It is a matter to which the attention of physicians needs to be frequently called. A man 26 years of age came to consult me last summer with every evidence of rapid consumption and enormous fatty liver. He had been ordered to go to Colorado. I advised his father to send him to a place nearer home, where, if necessary, he could be reached in a short time, or from whence he could return in case he desired to do so. At my instance he was sent to Kane, in the northwestern part of Pennsylvania, where he improved greatly during the first two weeks, taking long walks and sleeping well. Unfortunately, he did not control his appetite, and he made blood so fast that his blood-vessels could not stand the increased tension, and one day he was taken with hemorrhage from the nose and kidneys, and died in less than forty-eight hours.

I wish to take this opportunity of again mentioning Kane as among our available mountain health-resorts for consumptives. It is known by reputation to many physicians of this city, from the fact that some of our prominent physicians have been in the habit for years of sending patients there; but it is not so well known as it deserves to be. After personal investigation, I pronounce it better adapted for such cases than many more fashionable resorts, and the expenses are much less than at the latter.

There is one element which has not been referred to in the discussion, and that is that the patient is liable to be affected by homesickness. We know that a man in ordinary health may die with homesickness. If it is so depressing to a man in health, who has so many resources, how much more is it likely to be so in a sick person who is removed from his customary surroundings! This is another point in favor of health-resorts that are easily accessible, such as those mentioned by those who have preceded me in this discussion.

I should like to make a few remarks in regard to consumption, which, however, may sound a little heretical. This disease has been the subject of medical investigation for thousands of years, and in that time I think that we have reached some valid conclusions, based upon clinical and pathological studies, as to the best methods of treatment. These advances are not dependent upon, nor have they been disturbed by, recent progress in bacteriology, and they will remain the property of the profession after much of the recent interest in bacteriology has subsided.

I would particularly like to direct your attention to the fact that the value of climatic treatment was established before the present idea of contagion or particulate infection was thought of. Dr. Joseph Parrish, of Philadelphia, satisfactorily established the truth of this in his own practice and in his own person.‡ Permit me to state very briefly that, to my mind, consumption, as we use the term clinically, need not be a specific disease at all. On the contrary, there are cases in which it appears to be essentially a form of systemic degeneration or decay, a process of necrobiosis, and, in a broad sense, where it may be taken as an expression of a want of harmony between the human organism and its environment. It is the resultant of a large number of factors which cannot be considered at the present time, prominent among which are those which depress the vitality and which conspire to form the peculiar susceptibility or vulnerability which is universally acknowledged to exist. It has been well said by Dr. Keating, there are some patients who are in-

* New York Medical Journal, October 3, and Medical Record, January 17.

† Journal of the American Medical Association.

‡ The reader is referred to the Proceedings of this Society of March 22, 1882, for more extended consideration of this subject, in a discussion on the "Rational Treatment of Consumption."

capable of surviving in a cold climate. To such individuals the climatic treatment is just as applicable as taking a drowning person out of water and putting him on the land. Although man may live in all climates, yet all climates are not equally habitable by all men. Speaking broadly, each is adapted individually to inhabit a particular climate; a climate which is suitable for one class is unfit for another class: when the conditions are so unfavorable that acclimatization is impossible, the individual must die, and the mode of death in the majority of cases would, in all probability, be by consumption. As may be inferred from what I have said, I do not consider consumption as merely a disease of the lungs. In a large proportion of cases it is a disease of the whole organism, just as one form of Bright's disease is an affection of the entire system. The presence of a parasitic micro-organism in the lungs would in such cases constitute an incidental element, which, however, demands our consideration, since it may possibly influence both our therapeutics and our prognosis.

Dr. S. Solis-Cohen: I have but a few words to say in closing the discussion. Before adverting to the remarks upon my own paper, permit me to express my appreciation of the masterly essay of Dr. Wilson. I think he has very clearly shown what may be expected from change of climate, and what considerations should govern us in sending patients from home. The object of the plans of treatment which I have brought forward this evening is not to keep everybody at home, but simply to relieve those who either cannot get away at all, or can go away only for a very short time during the most unfavorable season at home. I have been much impressed by my experience with the benefit of out-door life, even in Philadelphia, and I insist upon patients going out to the Park or elsewhere, whenever the weather permits.

Dr. Neff has alluded to what is called "pneumatic differentiation." This is a new name for an old measure practised for a number of years. There is nothing new in the principle, though there may be in the mechanism of the particular appliance to which he refers. As our object, however, is to extend the benefits of pneumato-therapy to those who cannot afford to go away from home, I am not inclined to view with favor anything so preposterously exclusive and expensive as is that apparatus at present. Hauke, the first to construct a portable apparatus for compressed air, has devised a sort of pneumatic cuirass, by which the air about the thorax may be rarefied, the patient breathing either ordinary air, compressed air, or any desired gas or vapor. This is a cheaper and, I should think, equally efficacious means of accomplishing the same result. I did not allude to inhalations of rarefied air in the paper, because I referred to nothing but consumption. I can confirm the statement that rarefied air is of decided advantage in asthma. I did allude, however, in the paper to expiration into rarefied air. While a patient inspires compressed air from one apparatus, he may, by a little arrangement in the stop-cock, expire into rarefied air in another apparatus. This was advised by Waldenburg more than ten years ago. You can call it "pneumatic differentiation" if you choose.

In reference to the question of hemorrhage from breathing compressed air, it may savor of temerity to differ from him to whom I owe my knowledge of these subjects, but I have had two cases which do not support the proposition. One of these cases is that of a woman referred to me by one of the gentlemen present this evening. She is of exceedingly bad family history, two brothers and a sister having died in hemorrhage. She had had several attacks of hæmoptysis, and was much depressed in body and mind. She was put on the use of compressed air, and had no further hemorrhage until six months after the treatment was stopped. She then had two hemorrhages, and the treatment was renewed for a short time. Since then there has been no further bleeding. Her spirits are excellent, the pulmonary signs are stationary, and she has gained thirty pounds in about eighteen months. The other case is that of a man now under treatment for advanced phthisis. He had one or two hemorrhages prior to treatment by compressed air. Since its institution, some six months ago, he has greatly increased in flesh and strength, is able to attend to his business, and has had no further hemorrhage. I do not say it has prevented hemorrhage; but in these predisposed cases it certainly has not occasioned any loss of blood.

NEW YORK PATHOLOGICAL SOCIETY.

THE annual meeting was held January 13, 1886, the President, JOHN A. WYETH, M.D., in the chair.

REPORT OF THE COMMITTEE ON MICROSCOPY.

Dr. WALDSTEIN, of the Committee on Microscopy, said that the specimen presented at a recent stated meeting by the President was a tuberculous testicle; the other specimens presented by the President, being small tumors removed from the antitragus, were cartilaginous.

PERIOSTEAL SARCOMA OF THE RIGHT FEMUR.

Dr. A. G. GERSTER presented a portion of the right femur, the seat of a large periosteal sarcoma, removed by amputation from a girl 26 years of age. The patient had fallen down-stairs, but suffered no serious injury. From that time, however, she began to have difficulty in bending the knee and in going

up-stairs. A tumor formed over the outer condyle of the right femur, which Dr. Gerster believed to be a sarcoma. At one point there was some movement in the tumor which led Dr. Fluhrer to suspect enlarged popliteal glands, and Dr. Markoe thought it was probably an osseous growth with a narrow pedicle and mushroom-shaped top. Amputation proved it to be a periosteal sarcoma limited to the diaphysis.

MYXO-SARCOMA OF THE TESTICLE.

Dr. GERSTER presented a myxo-sarcoma of the testicle, the size of his fist, removed from a patient 32 years of age. The cause was obscure, as there was no history of injury or inflammatory condition to account for it.

OPERATION FOR PARTIALLY-DESCENDED TESTICLE, FIBROMA, AND HERNIA.

Dr. GERSTER presented specimens removed from a man 30 years old who since early boyhood had noticed only one testicle in the scrotum, When he was about eighteen years old a hernia appeared on that side; and, inasmuch as the patient could not wear a truss, on account of the pain which it produced, the hernia developed into rather large proportions. Within the past five years the patient noticed a body descend alongside the hernia, which probably was the atrophied testicle. Being unable to attend to his business, which required him to stand, he consulted Dr. Gerster, who found an incompletely-descended testicle and a hernia. There was a considerable portion of omentum which could not be completely reduced. At the operation, a body was found external to the sac, which proved to be fibrous tissue, the result of an inflammatory process. The sac was opened, the omentum, which was extensively adherent to the sac and inguinal canal, was easily dissected up, deligated in several pieces, cut off, and the stump replaced in the abdominal cavity. The sac was transfixed at its neck with a catgut suture, which could be compared to the string of a purse drawn tight. The sac was then cut off and the stump placed in the inguinal canal. The pillars of the external ring were brought together, leaving a little slit for the spermatic cord. The atrophied testicle was removed. The patient did well, and was afterwards dismissed from the hospital with the advice to wear a truss. Dr. Gerster thought a radical cure of a hernia of this size was doubtful, and with regard to so-called radical cure of hernia by injections, he did not believe it took place. Benefit, however, might result if the patient were enabled to wear a truss.

The PRESIDENT said, regarding the radical cure of hernia, that he had operated in about twenty cases, and he was certain of a cure in only one case in which he did Heaton's operation. He always advised the use of a truss subsequent to the operation.

RETENTION-CYST OF THE SUBMAXILLARY GLAND.

Dr. GERSTER presented a mucous cyst removed from the floor of the mouth of a man 26 years of age. It had been diagnosticated as a ranula, and an incision made into it through the oral cavity, by another physician, but the sac refilled, forming a tumor which seriously interfered with deglutition, and even with respiration. After extirpation, which was done in October last, the tumor was found to be a retention-cyst of the submaxillary gland. It had developed towards the median line, producing the impression that it might be a dermoid cyst. The facial and lingual arteries had to be deligated during the operation.

FIBROMA OF THE RIGHT VOCAL CORD REMOVED BY MACKENZIE'S FORCEPS.

Dr. C. H. KNIGHT presented a specimen which was removed from a man 47 years of age, who two years ago began to have trouble in speech and from coughing. During the operation hydrate of cocaine was employed. Six days after the operation the voice was natural.

CONGENITAL ABSENCE OF THE LEFT KIDNEY.

Dr. T. MITCHELL PRUDDEN presented the somewhat enlarged right kidney removed from the body of a man 22 years of age, who had given no symptoms of renal disease, and who had died with pulmonary phthisis and tubercular meningitis. The left kidney and ureter were absent, there being not even a rudiment of those parts. The specimen was worthy of presentation, as it was desirable to have exact statistical knowledge with regard to this malformation, as bearing upon nephrectomy. According to Gootmann, within twenty-five years previous to 1883 there had been but seventy cases of solitary kidney put on record.

Dr. W. M. CARPENTER saw, two or three years ago, at least three cases of absence of one kidney at autopsies made at Bellevue Hospital. He had seen no case before nor since. Dr. Welch found but one kidney in the body of a late New York surgeon.

Dr. W. P. NORTHRUP said that of a thousand autopsies on children he had found two thousand kidneys.

Dr. GERSTER had, in operating on a baby for imperforate anus, mistaken an enlarged ureter for the intestine, punctured it, and at the autopsy found it belonged to an only kidney.

SUPERNUMERARY MAMMARY GLAND.

Dr. A. JACOBI presented, in behalf of a candidate, a specimen removed from the left axilla of a woman 27 years of age. She first noticed a tumor about the fifth month of her third pregnancy. There also appeared a small tumor in the left breast, and, inasmuch as a near relative had died of cancer, she

feared that the disease was malignant. Dr. Jacobi, who saw the patient, diagnosticated a supernumerary gland in the axilla, notwithstanding the absence of a nipple. The tumor in the axilla was removed, and was found to be a chain of milk-secreting glands with no external duct or connection with the mamma of that side. After its removal the small tumor in the left mamma disappeared.

Dr. GERSTER thought that supernumerary mammæ in the vicinity of the axilla were more common than was generally believed, particularly in well-nourished women. They usually had an excretory duct leading to the mamma, but apparently they constituted a separate gland. A fact of some importance was that these axillary bodies sometimes became carcinomatous, the malignant process affecting the adjacent structure of the mamma proper secondarily. He mentioned such a case in which Dr. Waldstein made the microscopical examination for him.

Dr. JACOBI said that the remarks of Dr. Gerster made the candidate's case still more interesting. First, the woman was thin; secondly, she had not a very large mamma; thirdly, she had not noticed anything during her first two pregnancies, and it was only during the third that the tumor appeared.

Dr. WALDSTEIN remarked that, as Dr. Gerster had said, supernumerary mammæ were not very rare, but they nearly always had a nipple of their own, while in the case of the candidate there was none. He would also take the liberty of adding that during his examination of the specimen he found the axillary glands tumefied and containing cholesterin, showing that the milk secreted by the gland without a natural outlet was being cast out through the lymphatics.

GENERAL TUBERCULOSIS.

Dr. L. EMMET HOLT presented the lungs of a child, 4 months old, which died after a few days' illness, having tubercles in various organs of the body and slight pneumonic consolidation. The specimens were chiefly interesting in connection with the symptoms.

DIPHTHERITIC CROUP.

Dr. W. P. NORTHRUP presented a portion of lung from a child, showing the wide distribution of the membrane in membranous croup or diphtheritic croup. In the specimen presented the exudate occupied not alone the larger bronchi, but extended to within half an inch at most of the base of the lung. On looking over the records of the Foundling Asylum, in which this case occurred, he found the extent of distribution of the membrane given in sixty-one fatal cases of laryngeal diphtheritis or membranous croup: extending from the pharynx to the finest bronchi, twenty-two cases; from the pharynx to the bifurcation of the trachea, nine cases; from the larynx to the first division of the bronchi, twenty-one cases; from the larynx to the second division of the bronchi, four cases; to the fourth division, three cases; over the pharynx and trachea, two cases. In forty-nine cases croup was the first symptom; in twelve cases membrane in the pharynx was the first indication. Pneumonia occurred in forty-four cases.

Dr. Northrup also presented Dr. O'Dwyre's tube, used in the asylum for the relief of dyspnœa. Dr. O'Dwyre had spent five or six years in perfecting the tube, and it could now be used in private practice, although a little skill was required in introducing it through the glottis. It never failed to relieve dyspnœa in cases of croup. In the asylum they were accustomed to remove the tube once in about twenty-four hours, but the symptoms usually called for its replacement in a short time. A little of the milk given for nourishment would enter the tube, and after the act of coughing to expel it the child could breathe more freely and would go to sleep. Should the tube become clogged, severe coughing would cause it to be expelled. There had been only a slight loss of epithelium at the point where the end of the tube impinged upon the trachea; the vocal cords had not been affected.

At the executive session the following officers were elected: John A. Wyeth, M.D., President; T. Mitchell Prudden, M.D., Vice-President; Wesley M. Carpenter, M.D., Secretary; John H. Hinton, M.D., Treasurer; John C. Peters, M.D., Editor; Frank Ferguson, M.D., Assistant Editor; John C. Peters, M.D., T. M. Prudden, M.D., L. Emmet Holt, M.D., W. P. Northrup, M.D., and Louis Waldstein, M.D., Committee on Ethics; H. Marion Sims, M.D., and E. C. Wendt, M.D., Members of Committee on Publication.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held January 21, 1886, the President, A. JACOBI, M.D., in the chair.

REFLEX SYMPTOMS IN NASAL AFFECTIONS.

Dr. E. GRUENING opened the discussion on this subject with a paper on reflex ocular symptoms in nasal affections. The basis of his remarks was clinical observation. When we touch the nasal mucous membrane with the probe, reflex ocular symptoms will follow, such as lachrymation, conjunctival hyperæmia, photophobia, and sneezing; and nasal symptoms may be evoked in some persons by exposure of the eyes to a bright light. In a number of patients he found ocular symptoms, such as lachrymation, sensitiveness to ordinary light, and redness of the eyes, when examination of the eyes revealed no lesion which would account for the existence of such symptoms. For such cases collyria, hot and cold applications, etc., have been tried, but without benefit, whereas treatment directed

to the mucous membrane of the nose resulted in immediate relief of the ocular trouble. Dr. Gruening related the histories of a number of cases of ocular symptoms cured by treating the Schneiderian membrane. The cases did not include eye-symptoms which could be traced to extension of the nasal disease up the lachrymal duct. The treatment directed to the nose would depend upon the nature of the affection. Of course, all cases of ocular trouble would not yield to measures directed against an abnormal condition of the Schneiderian membrane, but he had a series of one hundred and fifty cases which justified him in drawing the conclusion that there existed a relation between the nasal and the ocular affection. Common features of the cases were burning and smarting sensation in the eyes, inability to fix vision, increased vascularity of the conjunctiva, absence of important lesion of the eyes and their appendages, and the inefficacy of treatment directed to the eyes, while the condition was relieved by measures adopted for the cure of the nasal disease.

Dr. T. A. McBride read a short paper in which he gave the histories of five cases of migraine and other neuroses which were relieved by treatment directed to the nose. He himself had not pronounced upon the nasal affection, but the cases had undergone treatment at his hands for the reflex symptoms, and, not being cured, the patients were seen by rhinologists who treated the nasal affection with the result of curing the migraine, supra-orbital neuralgia, gastric disturbances, etc.

Dr. Beverly Robinson read a paper limited chiefly to the connection between nasal disease and hay-fever, so called, and asthma. There were various other reflex disturbances occurring in connection with nasal symptoms of which he made mention. Regarding hay-fever and its connection with nasal disease, the results of operations for the nasal disease by Daily, of Pittsburg, and Mackenzie, of Baltimore, and many other rhinologists who had followed in their footsteps, offered abundant proof of such connection. While in many cases symptoms not directly connected with the nasal passages might disappear on instituting treatment for nasal disease, yet such cases did not occur sufficiently often to justify us in employing prolonged nasal treatment with the hope of curing secondary or reflex conditions. There must be an individual susceptibility before nasal disease would produce a reflex neurosis. First search should be made for other possible causes of the reflex phenomena, and, failing, we would then be justified in turning our attention to the nasal passages. This, however, did not mean that recognizable nasal disease should be allowed to go untreated. With regard to the question whether the sensitive area of the nasal mucous membrane was very limited or widely distributed, the speaker was inclined to take a middle view. He thought the continued use of cocaine spray would result in increased rather than diminished congestion of the mucous membrane. Dr. Robinson devoted a few remarks to treatment, and said that among palliative measures carbolic acid was a favorite remedy with him. But there were cases in which time spent in using palliative measures would be worse than thrown away, and we should proceed at once to use the galvano-cautery, etc.

Dr. Goodwillie continued the discussion, presenting some models of cases in which there had been deviation of the septum, exostosis, etc., causing various reflex symptoms. He also presented some instruments for operating upon the diseased nose.

The paper was further discussed by Drs. Baruch, Schweig, and the President.

The President had, during the course of a number of years, observed hundreds of cases of local choreic movements in children, such as blinking of the eyes, twisting the corners of the mouth, shrugging one or both shoulders (called bad habits), associated with chronic or subacute pharyngeal or nasal catarrh, or with conjunctivitis. Many such cases terminated in general chorea. Very often the rhinitis or pharyngitis began in the pharyngeal tonsil, a fact to which little attention had been called. He had always found chronic rhinitis associated with pharyngitis, or chronic pharyngitis associated with rhinitis. But it was not always necessary to treat the entire inflamed membrane: often treatment applied to a part would result in a cure of the general pharyngitis and rhinitis. Troutmann had very recently reported one hundred and fifty cases of enlarged pharyngeal tonsil, eighty-seven of which were complicated by hemicrania. Of the eighty-seven, all but two were cured by destroying in part or completely the enlarged pharyngeal tonsil. In one of the two not so cured there was a nasal polypus. It would seem that disease of any portion of the naso-pharyngeal cavity might give rise to the reflex symptoms alluded to during the discussion.

REVIEWS AND BOOK NOTICES.

The Principles and Practice of Medicine. By the late Charles Hilton Fagge, M.D., F.R.C.P., etc. Including a section on Cutaneous Diseases, by P. H. Pye Smith, M.D., etc., Chapters on Cardiac Diseases, by Samuel Wilks, M.D., and Complete Indexes by Robert Edmund Carrington, M.D., etc. Volume I. Philadelphia, P. Blakiston, Son & Co., 1886. 8vo, cloth, pp. 1040.

During the last twelve years of his valuable life Dr. Fagge was constantly occupied in preparing a Treatise on the Practice of Med-

icine, in which he intended to collect the rich results of his many investigations and large experience, basing it to a great extent upon his laborious researches into the pathological and clinical records of Guy's Hospital during the twenty years in which he was connected with this great metropolitan hospital as registrar, pathologist, and physician. Endowed by nature with wonderful powers of memory, he was familiar with modern medical literature, while his work in the wards and dead-house afforded him almost unequalled opportunities of obtaining extensive experience, which his numerous contributions to medical literature showed that he diligently improved. The results of this work appear in the System of Medicine to which he gave so much thought and labor. The first volume contains an Introductory Chapter defining disease, and discussing Symptomatology, Etiology, and Prognosis. This is followed by a section on General Morbid Processes, Contagion, Fever, Inflammation, Tubercle, Tumors, and Syphilis. Specific Diseases occupy the next section, followed by Diseases of the Nervous System, and Neuroses, while a section of Diseases of the Respiratory System concludes the work.

The style is lucid, interesting, occasionally familiar, even discursive, and the book, on the whole, is not only highly readable, but is a rich mine of experience. The judicious editing of Dr. Pye Smith has greatly enhanced its value.

LECTURES ON THE DISEASES OF THE NOSE AND THROAT. Delivered during the Spring Session of Jefferson Medical College. By CHARLES E. SAJOUS, M.D., etc. Illustrated with one hundred chromo-lithographs from oil-paintings by the author, and ninety-three engravings on wood. Philadelphia, F. A. Davis, attorney, publisher, 1885. 8vo, cloth, pp. 439.

This handsomely-printed and freely-illustrated work is one upon a subject in which the general practitioner is directly interested, since the habits of life of modern civilization make disorders of the upper air-passages among the most common ailments.

The technique of laryngoscopy and rhinoscopy is considered, with the instruments used for cleansing and medicating the throat and nasal cavities, and the several diseases of these portions of the body are considered, with the therapeutic applications. It is no small advantage that the plain, concise, though explanatory, language employed in lecturing before students has been preserved, and abstruse pathological discussions avoided. An exception, however, to this is made in favor of hay-fever, for which the author has suggested a new title, "Periodical Hyperæsthetic Rhinitis," which corresponds with recent ideas concerning the pathological process involved, and to a certain extent suggests its rational treatment. The treatment of various disorders receives a large share of attention, and the advice is judicious and based upon extended experience. The industry of the author is exemplified in the numerous drawings and oil-paintings from nature, which are reproduced by chromo-lithography and add decidedly to the usefulness and attractiveness of the book.

NEW REMEDIES AND CLINICAL NOTES.

THE TREATMENT OF PNEUMONIA BY QUININE.—F. P. Atkinson, M.D., says (*Practitioner*) that, "if the Collective Investigation Committee of the British Medical Association have done no other good, they have certainly directed attention to the treatment of pneumonia by quinine, which is destined, I think, sooner or later, to supersede all methods now in vogue. There can be no question that in almost every case (and I think there are very few exceptions) it prevents the disease advancing beyond the first stage, and rapidly causes resolution to take place. It does away with the necessity for poulticing, all that is required being the application of cotton-wool to the front and back of the chest. My friend Mr. Corbett, who has a good series of charts to bring forward, tells me it is equally successful in cases arising in young infants as it is in adult cases, and he asserts that many children he has been able to pull through would, in old times, certainly have been lost. He gives an adult two grains every two, three, or four hours, according to the case, combined with hydrobromic acid, and, if there is any delirium, a few drops of tincture of digitalis. If there is any large deposit of urates in the water, he gives some citrate of potassium alternately with the quinine. This method of treatment I have followed out with decided benefit to my patients and satisfaction to myself.

"Now, any one who has given repeated doses of quinine to a patient will, no doubt, have noticed the profuse sweating that occurs after its administration; and I am anxious to find out as to whether quinine really acts curatively through the perspiration it produces, or its antiseptic action, or both? In some cases of menorrhagia it exerts a very decided influence upon the muscular tissue of the uterus: has it any influence upon the muscular coat of the arteries in pneumonia? An answer to these questions would, no doubt, help us not only in the treatment of pneumonia, but also many other febrile diseases."

MERCURIAL INUNCTIONS IN PNEUMONIA.—In the *Voënna-Sanitarnoë Delo*, No. 26, 1885, p. 285, Dr. S. Sher, of Proskurov, Podolsk government, writes that the treatment of croupous pneumonia by local applications of

cold and by rubbing in gray mercurial ointment (two drachms daily) seems to be very effective, since it apparently relieves the symptoms and shortens the course of the disease, the average duration of the latter (from rigor to defervescence) being only five days. Of seventeen cases treated after this method, only one ended fatally. In five of the cases both of the lungs were affected.—*London Medical Record.*

The Prevention of Hydrophobia.—The *Indian Medical Gazette*, in commenting critically upon Pasteur's experiments, declares that the cases which had been communicated "are inconclusive in a high degree. Take Meister's, on which most stress is laid. It is not at all certain that the bite was effective, or that hydrophobia may not still occur. Altogether, these experiments, however interesting and sensational, are by no means devoid of serious fallacies, and, for the present, the prevention of hydrophobia must be essayed on other lines."

The Combined Effects of Morphine and Paraldehyde.—Morphine increases the effects of paraldehyde, as it does those of chloroform and chloral. It not only prolongs the sleep induced by efficient doses of paraldehyde, but renders small inefficient doses active. Thus the author found that one centigramme of hydrochlorate of morphine and one gramme and a half of paraldehyde, when given separately to a rabbit weighing about two kilogrammes, produced no hypnotic effect; but the same quantities given together caused deep sleep, lasting for several hours. Unlike chloral and other hypnotics, paraldehyde has no harmful secondary action. The simultaneous action of morphine and paraldehyde was found by the authors, in a careful series of experiments, to increase the frequency of the heart; the arterial blood-pressure is maintained, respiration being less frequent than in normal sleep. They recommend the mixture as a powerful hypnotic, not depressing the functions of respiration and circulation, but acting rather as a heart-tonic. The mixture, too, has the advantage of being a union of a hypnotic and an analgesic, and thus is indicated in many pathological conditions in which neither paraldehyde nor morphine can be given alone.—*Annali di Chimica Medico-Farmaceutica*, August, 1885: *London Medical Record.*

Aromatic Sulphuric Acid.—The addition of cinnamon to an alcoholic dilution of sulphuric acid was probably practised originally in order to increase its astringency; but it has been found that in the presence of sulphuric acid and oxygen this astringency is rendered inert. Catechu, on the contrary, is free from this objection, and has, according to R. Rother, the property of preventing such change over similar agents liable to these objectionable alterations, and he advises its addition to the officinal formula. The addition of cardamom he also recommends as a grateful and efficient aromatic, the short variety being the best. The following is the formula which he advocates:

℞ Pulv. cinnamon (Saigon), 2 troy oz.;
Catechu (air-dried), ½ troy oz.;
Cardamom, short, ¼ troy oz.;
Sulphuric acid, 6 troy oz.;
Alcohol and water, āā q. s. ad 2 pints.

"Bruise the cardamom, and separate the seeds from the capsules by means of a sieve. Then powder the seeds finely, and mix them with the cinnamon and eight fluidounces of alcohol. Macerate the mixture for two days, with occasional shaking; then filter, and follow with alcohol through the filter until eight fluidounces of filter are obtained. Reduce the catechu to a coarse powder, add eight fluidounces of water, and apply heat until the soluble portion is extracted, and set the solution aside for several hours. When this solution has thoroughly cooled and the catechu has crystallized out, pour the mixture into a filter and follow with water, if necessary, until six fluidounces of filtrate is obtained. Mix the sulphuric acid with one pint of alcohol by gradual addition and constant stirring, taking care to modify the temperature by appropriate means of refrigeration. To this mixture, when cooled, add the aromatic tincture, followed by the catechu solution; then set it aside for several days, and filter.—*Druggists Circular and Chem. Gazette.*

MISCELLANY.

Dr. Piffard has retired from his editorial connection with the *Journal of Cutaneous and Venereal Diseases*. The *Journal* will be continued under the sole editorial charge of Dr. P. A. Morrow. We may remind our readers that this is the only publication in the English language devoted to skin and venereal diseases, and during the three years of its existence it has won for itself a high reputation for scientific excellence as well as practical utility. In addition to presenting all that is new and valuable in these special departments, the colored lithographs and wood-engravings with which the original articles are illustrated are worth more than the price of subscription.

Ligature of the Femoral Artery under Cocaine.—Dr. Joseph W. Howe ligatured the femoral artery for popliteal aneurism, under cocaine, at St. Francis' Hospital, New York, January 27.—*The Medical Record.*

Dr. Du Claux has been appointed to the

chair of Biological Chemistry in the Faculté des Sciences.

DR. VULPIAN has resigned his position as physician in the Paris hospitals.

HARVARD MEDICAL DEPARTMENT.—Dr. W. L. Richardson has been appointed professor of obstetrics.

PERSONAL.—Dr. H. Earnest Goodman has removed to No. 1509 Walnut Street, Philadelphia.

NOTES AND QUERIES.

GRATUITOUS MEDICAL SERVICE FOR THE INDIGENT INSANE.

IN this age of progress and enlightened civilization it is a reassuring guarantee of real advancement to observe the growing tendency on the part of the more intelligent, powerful, and highly-favored classes of the community to extend the assisting hand to those less intelligent and less fortunate, whose daily hand-to-mouth struggle for subsistence is sufficiently precarious and uncertain even when bodily and mental vigor is retained. The invasions of disease, to which depressing social conditions and unsanitary surroundings render them peculiarly liable, rapidly recruit the numbers of those depending upon charity. While provision for the care and medical treatment of the indigent sick has been liberally made by the establishment of general hospitals and of free medical dispensaries for physical maladies and disorders, until very recently no effort has been made to provide gratuitous advice and medical treatment for the indigent insane. The Board of Managers of the Pennsylvania Hospital have come forward and supplied this deficiency by the establishment of such gratuitous service in the Out-Patient Department of the general hospital. It is designed to reach more particularly cases of mental disorder in their incipiency whose condition does not demand custodial care. In regard to this branch of the hospital service it is sufficient here to say that during the past few months since its commencement the applications for advice and treatment from proper cases have been sufficiently numerous to forecast a career of future usefulness.

The question will naturally arise, Does a demand really exist? is there any considerable number of cases of incipient or of threatened insanity among the poor of our community? This will be best answered from the future experience of the service already established, as it will serve to test the requirements of the public in this matter. It would seem as though the demand was most pressing, when viewed in the light of the great and ever-increasing number of requisitions for admission made upon our already overcrowded public asylums for the insane by this very class. Nor are these demands made solely upon State hospitals: the charitable capabilities of our private institutions are strained to the utmost limit in response to almost daily applications for admission of acute cases of mental disorder among the poor. Let it be granted that the large majority of these have passed the stage during which it would be possible to benefit them by dispensary treatment; that they already require custodial care. Yet the time was when their disorder was incipient, threatening, impending; and the fresh recruits to this army of unfortunates must be constantly coming in.

The offer of gratuitous relief of *incipient* insanity takes a long step in advance of the benefits extended by our hospitals in the past, meets the patient at a remote point upon his way to the institution with some reasonable hope of averting the impending danger and restoring him to a condition of health and usefulness. Too frequently their improvable period has passed by neglected, or their chance for speedy recovery has been much impaired prior to the time of hospital commitment, due in part to the absence of facilities for advice and treatment, to a failure to recognize the character of the disorder, or to a natural and popular prejudice against fixing the supposed "stigma" of insanity upon the patient by placing him in a hospital. These untoward influences would be much less likely to operate in a dispensary service, especially should the latter be connected with a general hospital and not (apparently) with an asylum. The insane will come, or their friends will bring them, to a department where the subjects for treatment in general medicine, surgery, gynæcology, ophthalmology, and mental disorders are treated gratuitously in the same or in contiguous apartments, with much less dread and hesitation than they would exhibit if invited to present themselves for treatment at an asylum. In offering such service with the hope of actually reaching this class and alleviating their morbid conditions, it is necessary to meet them upon their own ground and make proper concession to popular prejudice.

A properly-conducted free service might do much in the course of time, by preventive medical treatment, to diminish the great pressure of applications for admission upon our public institutions. Here in this district, noted for philanthropy, the public room for the care of the insane poor is inhumanly overcrowded; nor will extensions of present existing buildings suffice to abate this evil It demands, in addition to this, a new hospital, furnished with the best modern appliances for the fulfilment of its purposes, in order to begin to meet the actual requirements of the case. Even were this accomplished, in a very few years the accommodations provided would again be found insufficient. Is it not time, then, to at least attempt to apply prophylactic therapeutics and hygiene to impending insanities? It is the "ounce of prevention" which, in this instance, is worth more than any weight of alleged "cure." This service would afford an interesting study of the effect of treatment of these partially-developed pathological conditions. As the records were extended, a quite new field of clinical facts would be at the disposal of those who comparatively seldom have an opportunity of treating a case of incipient insanity, although in daily contact with its later and less hopeful manifestations.

It might not be out of place here to indicate some of the forms of mental disorder likely to present for advice at such service. Prominently first in point of frequency would be those showing that group of symptoms which picture to the mind impending melancholia. The ambitious, feverish struggle for precedence which seems to pervade all classes of the community, the absence of proper thrift, the living fully up to or beyond one's means, however small they may be, and the disappointment and embarrassment which are almost invariable accompaniments of such a mode of life, are responsible for much of the over-anxiety and mental depression found in the middle and lower classes. Grief, shame, disappointed ambition, pecuniary reverses, domestic infelicity, and the depressing effect of hard toil for a scant subsistence are some of the many exciting causes. Melancholia seems to be, at present, the most prevalent type of acute insanity. That worn-out and broken-down condition which has received the name neurasthenia would also be frequently encountered, as would insomnia in its many forms, occurring as an isolated morbid condition or as a troublesome symptom of other and graver affections. Less frequently would be met cases of mania, more or less advanced, chronic insanities, syphilis of the brain, paretic dementia, epilepsy, mental disorders of traumatic origin, those dependent upon vascular defects, upon the abuse of stimulants, the habitual use of drugs, and those the result of imperfect or arrested development.

The knowledge of the existence of such a charity should be widely diffused in order to reach those for whose relief it was founded, and the medical fraternity of our city could doubtless render valuable assistance in the cause, not alone by the general diffusion of information and the recommendation of special cases, but in the equally important task of educating the public mind to a higher level of appreciation of its duties and responsibilities towards its insane.

Should it be found in the future that free service for these disorders declined through lack of patronage, it would not indicate that insanity is not prevalent, nor that mental diseases have not distinctly recognizable initial stages, but that popular education and enlightenment would have to advance a step higher in order to appreciate the public-spirited efforts in its behalf of those who builded ahead of their time.

HENRY M. WETHERILL, JR., M.D.,
Pennsylvania Hospital for the Insane.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 17, 1886, TO JANUARY 30, 1886.

COLONEL JOHN E. SUMMERS, SURGEON.—Retired from active service, by operation of law, January 24, 1886. S. O. 20, A. G. O., January 25, 1886.

MAJOR WARREN WEBSTER, SURGEON.—Sick-leave of absence further extended nine months on account of sickness. S. O. 15, A. G. O., January 19, 1886.

MAJOR WILLIAM E. WATERS, SURGEON.—Granted leave of absence for one month and fifteen days. S. O. 5, Division of the Atlantic, January 23, 1886.

ASSISTANT-SURGEON J. M. BANISTER.—Ordered for temporary duty at Fort Warren, Massachusetts. S. O. 16, Department of the East, January 23, 1886.

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, FEBRUARY 20, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE ON HEREDITARY SYPHILIS.

BY J. M. KEATING, M.D.,

Visiting Obstetrician to Philadelphia Hospital, and Lecturer on Diseases of Women and Children, etc.

Reported by WILLIAM A. EDWARDS, M.D., Medical Registrar Philadelphia Hospital; Instructor in Clinical Medicine, University of Pennsylvania.

GENTLEMEN, — The wards of the hospital are so peculiarly rich in illustrations of the interesting and important subject of hereditary syphilis that we will devote several meetings entirely to its consideration.

Syphilis is a disease that you will meet with in all walks of life,—in the homes of the rich as well as in the abodes of the poor. In some cases its symptoms are so well marked that he who runs may read; in others but irregular manifestations and ill-defined symptoms will warn you that your little patient is the subject of this most unfortunate inheritance.

By hereditary syphilis we understand syphilis which has been transmitted by either parent before the seventh month. This matter of transmissibility is one of great interest, and many theories have been advanced by different observers in attempts at elucidation; but as yet it may be considered an open question. Some authorities are of the opinion that men with tertiary syphilis may procreate non-syphilitic children; others add their quota to the argument by stating that tertiary syphilis is not any more transmissible than it is communicable in other ways.

The weight of opinion seems to support the view that, after four years of careful, conscientious specific treatment, the danger of transmission of syphilis to offspring is at the minimum, if it exist at all.

It seems also to hold good that, even if both parents are infected, but have reached the tertiary stage, the danger of transmission is small. My personal opinion is that we should be extremely careful in recommending matrimony to syphilitics. An extended practice in pædiatrics has convinced me that many cases of late syphilis are not seen by syphilographers, but by the general practitioner,—as, for example, late eruptions and scrofulous troubles. Some authorities consider many cases of scrofula as glandular syphilis. A notable and able exponent of this view was the late Professor Gross.

As we have seen above, syphilis reaches the child either through the mother or father or by direct infection, and the little being is brought into the world a subject of hereditary syphilis, ready to infect all but its mother. This is in accordance with the well-known "law of Colles," which is about as follows: "a child born of a mother who is without obvious venereal symptoms, and which, without being exposed to any infection subsequent to its birth, shows the disease when a few weeks old,—this child may infect the most healthy nurse, whether she suckle it or merely handle and dress it; and yet this child is never known to infect its own mother, even though she suckle it while it has venereal ulcers of the lips and tongue." This law seems to show that, in all probability, the mother has a latent form of syphilis which renders her incapable of receiving the disease, she having possibly contracted her disease from the fœtus from an ovum becoming impregnated by a syphilitic spermatozoid. Colles's law shows us how extremely careful we should be in allowing patients to select wet-nurses. Unless you interfere, a perfectly pure nurse may be infected with this most unfortunate disease. You will not infrequently see chancres on the nipples of wet-nurses contracted in this way.*

The mother may have received the syphilitic infection previous to conception of her child, or at its conception, or again during the period of utero-gestation. It is proper for me to state that syphilis by conception has been denied by several eminent authorities; but the great mass of clinical facts, and, indeed, the experience of this hospital, seem to show the frequent, if not the almost invariable, contamination of the mother through the fœtus. You will readily appreciate the fact that this subject of infection through the medium of the fœtus is a difficult one to pursue,—so many stumbling-blocks are

* I am not prepared as yet to claim entire allegiance to the law of Colles, nor do I believe that every woman who gives birth to a syphilitic child is of necessity syphilitic herself. Diday recognizes the fact that many women who bear children to syphilitic fathers escape contagion altogether.

met with in your investigations. It would first be essential to assure yourself that the father has no abrasions or any apparent avenue by which the virus could be conveyed to his wife; again, that the wife is not presenting some evidence of active syphilis, in some apparently trifling or unnoticed lesion. Having assured yourself of this, then there is but one means of transit from the father to the mother, and that is through the fœtus. The law of Colles would again be an argument in favor of this view. I have never, in a long service in this hospital, so peculiarly rich in syphilitic diseases, seen a chancre on the nipple of a mother who has given birth to an infected child, because the mother has probably acquired immunity by first acquiring the disease.

An interesting clinical point sometimes seen in the wards is that, when syphilis occurs during utero-gestation, the first manifestations occur at a time corresponding to that which we know intervenes between the source of ordinary contagion and the appearance of the symptoms,—*i.e.*, about the ninth or tenth week of gestation; allowing, of course, in these cases a little longer period of incubation.

In some cases it seems to be almost an undoubted fact that the father has transmitted syphilis to the child directly, without infecting the mother. Remember, also, that a woman who conceives while perfectly healthy may contract syphilis during utero-gestation and the child be born with congenital syphilis. The contagion in the mother may be as late as the seventh month of pregnancy. The month at which a fœtus will escape infection is not settled beyond peradventure. The general opinion is, however, the earlier the mother receives her infection, the less likelihood there is of the child escaping.

If both parents have syphilis, there is, of course, absolute certainty that the new being will also have it. The more recent the disease of the parents, the greater, of course, would be the chances of transmission in a grave form. The hereditary transmission of syphilis becomes less as the parents grow older. Correct treatment will also modify the transmission. That a pregnant woman or her husband is the subject of syphilitic disease is shown in many ways. Early abortions (from the first to the sixth month) are a frequent indication, due, in all possibility, to syphilitic disease of the placenta. The fœtus will generally present evidences of the disease in the palms and soles, and in visceral lesions. Many cases will present no distinctive lesion. Almost all of these syphilitic products will be macerated and of a purplish, congested color, with the skin detached or detachable. An eminent authority states that at least one-third of the syphilitic children are dead-born. A syphilitic babe will manifest its diathesis at variable periods after birth, rarely later than the third month.

The first symptom will probably be "snuffles," which will greatly interfere with nursing. This is due to inflammation of the mucous membrane, and may even extend to ulceration of the Schneiderian membrane, eventually involving bone and cartilage. The child will generally have a harsh, disagreeable cry, such as you have heard in these babies. This is due to an inflammation of the mucous membrane of the larynx, and is very characteristic. You will occasionally meet babes who present syphilitic pemphigus of the palmar surfaces. This at one time was considered by many observers as not diagnostic or characteristic of the syphilitic taint, but now almost all observers agree in relegating pemphigus to a prominent place in the chain of evidence going to make up the diagnosis of hereditary syphilis. It is not necessary that these children should be senile-looking. Last year I showed to the class an infant suffering from gummatous growths who was fat, plump, and apparently well nourished. The rapidity of the emaciation is usually in proportion to the amount of poison transmitted.

Erythema, roseola, and papular eruptions will now manifest themselves, as there is present a condition of general hyperæmia with papillary infiltration.

Erythema, sometimes called roseola, will generally present itself about the third week after birth, and is most apt to commence on the belly in irregular spots or patches, red in color, and disappearing on pressure. The eruption will extend to the trunk and limbs, and become darker in color. The eruption may be excoriated, or, if not, at least moist, due to the thin epidermis at this period of life. You may also meet it confluent.

Do not mistake this eruption for the simple non-specific erythema of infancy. The syphilitic roseola is liable to become

scaly on the palms and soles. Another manifestation of absolute diagnostic aid is the mucous patch and the papular eruption, the former occurring on the tongue, lips, and cheeks, and at the angle of the mouth at the muco-cutaneous junction.

The papules will be the larger and more marked at those situations at which there is the most heat and moisture, as in the groin, flexures of the joints, and the genital organs. When these papules are thus kept warm, soft, and moist, they may present a fetid discharge and look not unlike condylomata.

The mucous patches, however, will claim most of your attention. They are rarely absent in these cases, and are usually the mode of conveyance of the poison from the syphilitic babe to the non-infected nurse, or, in fact, to any one who comes in close or intimate contact with the little patient. In appearance they do not differ much from the same lesion in the adult, which you have so often seen in this hospital, except perhaps that they are apt sooner to lose the surface epithelium.

You will generally note them as irregularly red, depressed spots, either distinct and separate or running one into the other, sometimes ulcerated, and covered with a false membrane.

Their point of selection is interesting, being generally, as above stated, the angles of the mouth, dorsum, or border of the tongue,—points which you know are rarely affected by non-specific stomatitis, the latter generally occurring in the gums or in the depression between the gums and the cheeks, which, in turn, are points rarely invaded by mucous patches.

This little patient's back will well illustrate the ravages of pustular syphilide, an eruption which appears in the secondary period, usually at or about the sixth week. In these cases the papules are metamorphosed into pustules. The transformation is slow and sluggish, and your patient is apt to present the two eruptions, papular and pustular, with transitional stages between the two. These pustules will leave behind ulcerated surfaces, and eventually form a permanent cicatrix.

Furuncles may or may not occur. They are of doubtful diagnostic value.

This, gentlemen, shows you the picture of a syphilitic child from birth up to the end of about the first year, at which point we will leave it until our next meeting.

ORIGINAL COMMUNICATIONS.

A CASE OF DIFFICULT DIAGNOSIS.

BY HUGO ENGEL, A.M., M.D.,
Professor of Nervous Diseases and Clinical Medicine in the Medico-Chirurgical College of Philadelphia.

MEDICAL science and art are really making astonishing progress, and especially is this true with reference to medical diagnosis. The physician no longer relies only upon verbal inquiry or the visible symptoms, or the result of his examination of the conditions of the patient's pulse and tongue, but he employs exact methods and instruments of precision, and the information thus obtained cannot deceive the trained observer.

The truth to-day is well recognized that in many cases an exact diagnosis is impossible without the employment of modern means of investigation,—the thermometer, ophthalmoscope, electrical apparatus, dynamometer, æsthesiometer, stethoscope, and other means of precision. With such assistance, one might think it impossible for any disease, no matter how obscure, to escape detection, but this is by no means invariably the case. While we admit that a competent physician but rarely meets with a case the pathology of which he would not understand after a thorough examination, at times cases of a well-known disease escape recognition during life. Some maladies which medical science has thoroughly investigated, and with which a trained diagnostician ought to be so familiar that he should at once detect them, occasionally appear under such peculiar circumstances, and are attended by such conflicting symptoms, that it is almost impossible to determine their nature at the time.

While I do not doubt that during a professional career of about twenty years I have committed many a diagnostic error, yet three times have I failed to recognize one and the same disease, which, strange to say, each time was presented in a similar manner. The first two cases happened early in my professional life,—so early that I had completely forgotten them, and that only their description in my records brought them back to my memory; but the third came under my observation only a few months ago, and it was a surprise to me, on looking over my records, to find that seventeen years before I had attended two similar cases within one year.

The case is so instructive, and its publication might lead to the avoidance of so many errors, that I have concluded to report it; for it has always been my opinion that we would learn more from the publication of our mistakes than from the recording of rare cases. The history of the case in question is as follows:

P. B. C., æt. 50, first came to my office August 6 of last year, and he then gave me the following history of himself and family. When he was but seven years old his father and mother both died within one week of each other with typhus, then epidemic in the Prussian barracks, where his father was stationed. Of his childhood he can only say that he never suffered from any disease that he is aware of. Later, he continued in the best health until about one year ago, when he had some fever, headache, and a papular eruption, which symptoms, however, all ceased within three or four days.

When I first saw him he appeared to be a robust man of compact build. He came to consult me about difficulty of breathing, which, as he said, had commenced one month previously. When he awoke one morning he had had a dry, barking cough, with pain and soreness beneath the sternum, which he attributed to a cold. He consulted a physician, who told him that he was suffering with bronchitis. The complaint was not serious enough to prevent him from attending to his business, which was that of an upholsterer, he being the owner of a large furniture establishment. Notwithstanding treatment, the cough did not seem to improve; but at the end of the first week difficulty of breathing was added, and this remained more or less stationary, and always became worse at night. He then also noticed that he had to pass water frequently, and in large quantities, while his bowels evinced a strong tendency to constipation, something very unusual with him. He also had great difficulty in falling asleep: a peculiar restlessness seemed to overcome him at night, which, in conjunction with the dyspnœa and the frequent micturition, probably caused his wakefulness. When the dyspnœa was most severe it assumed the character of asthma, the wheezing within his chest being perceived by all present in the room. The disturbance in the secretion of urine commenced immediately after he had taken the first dose of a medicine which his first physician had given him for the relief of his cough.

At his first visit I noticed a papular eruption in his face, and found that the same exanthem, though more isolated, extended all over the body. The papules were moderately red, small, and very hard; at many places, mainly on the abdomen and back, they had given rise to bleeding in consequence of the scratching, for the itching at times became intolerable, especially towards night. This was the same skin-disease as that which had attacked him the year before, but it had then yielded to treatment or disappeared by itself within three or four days.

There was a peculiar restlessness about Mr. C. It seemed difficult for him to sit still. When asked about it he replied that he felt "a something" in his legs which forced him to change their position every few seconds. Though the appearance of the patient was that of a robust man, the skin of his face had a spotted look; a bluish discoloration here and there indicated some obstruction in the circulation, or a want of sufficient aeration of the blood. On inquiry, Mr. C. also informed me that four weeks ago, just before the beginning of his illness, he had had occasion to get himself weighed, when he found his weight to be exactly two hundred and thirty-two pounds. A few days before he came to me he noticed that his clothing was becoming too wide for him, and, anxious to know whether he had really lost so much flesh, he again weighed himself, when to his surprise he discovered that he had lost forty-two pounds. Being only five feet nine inches tall, the one hundred and ninety pounds remaining made him still appear a stout man.

Having obtained the above information, I proceeded to a physical examination. Percussion all over the chest revealed a clear sound, while on auscultation many sibilant and large and small moist râles were heard over both lungs. These râles were about evenly distributed; the respiratory murmur was not clear, there being more of the bronchial element in it, and expiration, though faint, appeared slightly prolonged. A very important result was obtained from respiratory percussion, although to my regret I did not attach that significance to it which later events warranted. Everywhere over the lungs and slightly more over the apices the clearness of the percussion-note seemed to me to become impaired on letting the patient take a deep breath and hold it while I percussed. The deeper the inspiration and the longer the air was retained within the chest, the more the sound appeared to me to lose its clear resonance, though it at no time became positively dull.

Spleen and liver were somewhat enlarged; the tongue, slightly coated, evinced a tendency to dryness; the pupils were contracted, but reacted well; and the skin was deprived of its normal moisture. The heart was normal, but the impulse slightly weak and the action rapid; temperature 99° (2 P.M.); number of respirations 32. The examination of the urine gave a negative result.

As the patient seemed to suffer mainly from the cough and the dyspnœa,—the latter becoming worse on the least attempt at motion,—I prescribed the following mixture:

℞ Antimon. et potass. tart., gr. ij ;
Liq. ammonii acetatis, f℥ij ;
Spirit. æther. nitrosi, f℥ij ;
Syrup. pruni Virgin., q. s. ad f℥vj. M.

S.—A teaspoonful in water every two hours.

I also ordered,—

℞ Pulver. Doveri, gr. x ;
Quininæ bisulphatis, gr. v.
M. Ft. pulvis. S.—At night.

I also told him to have as many dry cups as possible applied all over his chest, and to take a moderate dose of Glauber's salt one hour before breakfast,—just enough to keep his bowels open,—and regulated his diet.

Four days later the patient again called on me, and from the manner of his breathing I at once saw that a great improvement had occurred, which did not surprise me, as I had often known a bronchitis to disappear within a few days under the use of tartar emetic and dry cups. The patient acknowledged that he felt a great deal better, that the dyspnœa had completely ceased, and that he slept as well as ever. When I advised him to continue the medicine in a diminished dose and at longer intervals, and to see me again in three or four days, he seemed astonished, having evidently believed that he could dispense with the professional services of a physician.

He did not visit me again until a week afterwards, when I noticed a great change in him. He looked paler and thinner, and seemed much weaker. He said that he now regretted not having obeyed directions, but that he had been feeling well until the day previous, when a short cough commenced to trouble him and some of the dyspnœa returned. But what he most complained of was a diarrhœa, which had set in a day earlier. He had had only from three to four fluid passages during each twenty-four hours, but, what was remarkable about them, they left him very weak, and since the first movement of the kind he felt a peculiar debility in his lower limbs, especially from the knees downward. The frequent desire to urinate had also returned, and the quantity of the urine excreted again augmented.

There was no change in the physical condition of his chest, as revealed by percussion and auscultation. The same râles, only less numerous, as heard at first, were still perceived. An examination of the urethra proved the absence of all morbid conditions there. I instructed him to measure the exact quantity of urine passed during twenty-four hours, and to bring me a specimen of it. For the diarrhœa I gave him twenty grains of subnitrate of bismuth, with one-sixth of a grain of morphia, half a grain of bicarbonate of sodium, and one grain of aromatic powder, to be taken once every five hours. As soon as the diarrhœa should have ceased he was to resume the tartar-emetic mixture.

Four days later he again called on me. The dyspnœa had once more subsided, and the diarrhœa decreased to one fluid stool daily, but the latter always left him very weak. In other respects Mr. C. had not improved. He was evidently losing flesh rapidly. He reported the quantity of urine passed during twenty-four hours to have been three quarts and a few ounces, and its chemical examination revealed a trace of sugar. I sent a specimen of it to Mr. Louis Koch, a very reliable apothecary and most excellent chemist. He also found a trace of sugar, but no other foreign substance, in the urine.

I prescribed half a fluidrachm of ergot to be taken three times a day, and one-eighth of a grain of morphia in the morning and at night. Under this treatment the amount of urine secreted gradually diminished to three and a half pints daily, and the sugar disappeared in the urine. But otherwise, while the dyspnœa greatly improved, the diarrhœa continued, the patient having from two to three loose discharges daily, and each of them left him weaker. As I had found this condition,—a diarrhœa in which the discharges are fluid, but very small in quantity, which seems to be uninfluenced by the usual treatment, and which causes in the patient a feeling of great weakness utterly out of proportion to the small quantity of fæces discharged,—especially if associated with an increasing debility in the lower limbs, and if accompanied by rapid loss of flesh, only in phthisical patients suffering from tubercular ulceration of the bowels, I once more made a most careful physical examination. The percussion-resonance was normal all over the chest, but its diminished clearness on respiratory percussion—a diagnostic test which we owe to Professor Da Costa—seemed to me now more apparent than at first. Auscultation revealed many small moist râles, but no crackling anywhere. Spleen and liver also were more enlarged.

It was now that the idea first occurred to me that the patient might be suffering from miliary tuberculosis ; and, as I had found the fluid extract of coto, in doses of twenty drops administered every three or four hours, the only reliable remedy to put a stop to the diarrhœa in tubercular ulceration of the intestines, or at least to influence it, while in the fluid alvine discharges due to some other morbid lesion it had proved useless, I concluded to employ this remedy as a test. As the patient's pupils were rather contracted, I also prescribed a solution of atropine, told him how to drop it into his eye, and requested him to call again in four days for an ophthalmoscopical examination, my desire being to see whether I might not there find an evidence of the tubercular disease. I further gave him my thermometer and instructed him in its use, so that he might keep a record of his temperature.

Two days later (the patient resided in a suburb of Philadelphia) he sent his daughter to me to report his condition, as requested. She said that his diarrhœa had ceased, and that, though still very weak, he was apparently improving. His temperature-record had meanwhile been as follows:

August 28, 1885, 7 P.M., 100°.
" 29, 1885, 7 A.M., 99°.
" 29, 1885, 7 P.M., 100.1°.
" 30, 1885, 7 A.M., 98.4°.

I now felt sure of finding the proof of tuberculosis on my examination of his eyes, but that was destined never to be made. The following morning, at 6 A.M., I received a despatch at once to come to Mr. C., who was dying. When I arrived at his house, two hours later, he was in a comatose condition, the attack having occurred a little after five the same morning. About forty-eight hours later the patient died, evidently under the symptoms of gradual compression of the brain, probably due to serous effusion. There was no urine excreted during the last two days, the bladder being empty. The dyspnœa was great, and ultimately assumed the character of Cheyne-Stokes respiration. The temperature during this time vacillated between 99½° and 101°; but an hour before death, when the pupils, which in consequence of the mydriatic had at first been dilated, and later, after its discontinuance, had become contracted, were widely dilated, the thermometer recorded 97.3°, and the pulse was very irregular. During the whole agony there was a great accumulation of mucus in the chest, which, in consequence of the gradually increasing paralysis, the patient could not expectorate. This long-continuance of the "death-rattle" made the scene at the death-bed a very sad one.

I received permission only to open the chest. Millions of miliary tubercles were strewn all over both lungs, and they were especially numerous at the apices, thus explaining the result of respiratory percussion. The heart was flabby, but otherwise normal; so also were the large blood-vessels. As I had solemnly promised not to push my investigations further, I can only tell the condition of the liver, which was swollen and of very dark hue.

After the patient's death I obtained some information which caused me to believe that C. for many years had been suffering from diabetes mellitus, though in a very mild form and one that only at long intervals presented the more characteristic symptoms of the malady. His family had noticed at times a very peculiar odor from his urine, somewhat sweetish, which reminded one of new-mown hay: it was so strong "that the whole room retained the scent," said his wife, who had also remarked that at these times her husband passed unusually large quantities of water. The peculiar papular eruption so often met with in diabetes, and of which the patient had complained a year previous to his death and at the time of his last illness, would also tend to confirm the view taken.

The malady, however, causing his death was miliary tuberculosis; but it presented a picture which might well cause an error in diagnosis. First, it is rare that the disease attacks a man of apparently robust health at the age of Mr. C., or that it runs so rapid a course while the individual attacked is still able to move about, and indeed only seeks his bed two days before death. Then these very acute cases show, almost invariably, a different temperature-record. It generally is very high, from 104° to 105° Fahr., and usually assumes an intermittent type, while the symptoms are apt to simulate those of typhoid fever.

When the patient first came to me there was no proof of the existence of diabetes, for, though the examination of the urine was carefully made and the test the same as that applied later, no excess of sugar was found, and the quantity secreted was not augmented. There was at the start nothing to warrant any other diagnosis than that of bronchitis accompanied by dyspnœa, a form of inflammation of the bronchial tubes frequently met with in stout persons in whom the love of good things has gradually brought about a flabby or fatty-degenerated heart. The physical examination confirmed this diagnosis, and the result of treatment did so still more.

There really were but two or three symptoms, which, had they at once received their correct interpretation, should have cleared up the case: (1) the change on respiratory percussion, (2) the rapid loss of flesh, and (3) the nature of the diarrhœa.

Respiratory percussion, though easily enough performed, is difficult to interpret. Generally the diminution in clearness is by no means very marked; and should it not be at once recognized,—*i.e.*, at the first or second attempt,—the examination had best be postponed to the next visit, for on repeated tapping the ear is apt to become accustomed to the sound and can no longer distinguish fine differences. I

am convinced that any deposit sufficient to diminish the elasticity of the air-cells, without being enough to encroach seriously upon their interior so as to give rise to marked dulness in consequence of the absence of air, has the effect of altering normal resonance on respiratory percussion. The latter is therefore a valuable diagnostic aid, provided we succeed in interpreting its result correctly.

The rapid loss of flesh might have been explained by the diabetes, for, as the fatal end approaches, patients suffering from this disease usually lose weight rapidly. But in C.'s case there was no symptom indicating the near approach of death until a few days before his end. But whenever a person with apparently only a bronchial affection continues to lose decidedly in weight, we ought always to be suspicious of a grave cachexia.

The one sign, however, which, no matter how doubtful the result of the physical examination, invariably proved to me the existence of a tubercular diathesis, and which in this case also first caused my thoughts to turn in the direction of phthisis, was the peculiar diarrhœa. The patient usually has at the beginning only three or four stools a day; though fluid, they are sometimes exceedingly small and never large in quantity, but the desire for evacuation sets in so suddenly that the patient scarcely has time to reach the water-closet. Most characteristic, however, of this diarrhœa is the great debility which the patient feels immediately after evacuation. This weakness usually attacks his lower legs, and stands in no relation whatever to the quantity of the alvine discharges. A diarrhœa with exactly the same peculiarities I have never met with unless it was due to tubercular ulceration of the bowels. I do not wish to be understood as saying that this lesion is always accompanied by such diarrhœa; but what I contend is, that this diarrhœa, when present, is pathognomonic of the disease. Another important point distinguishing the diarrhœa from other fluid intestinal discharges is the fact of its being uninfluenced by any of the usual remedies,—neither opium nor its alkaloids nor astringents having any effect either upon the frequency or the character of the evacuations. The only drug that may be said to often at once ameliorate this symptom is the fluid extract of coto, as mentioned in the beginning of this article.

Regarding the weakness attending this diarrhœa, special stress must be laid upon its occurrence immediately after the alvine discharge, for though naturally the patient is not strong, he always specially feels the debility at the time mentioned.

The description of the case of C. will convince any physician of the difficulties which prevented an immediate correct diagnosis; and, while drawing the attention to the errors to be avoided, it also indicates the points which, if rightly interpreted, enable us, even under such adverse circumstances, to recognize the real malady. The case also reminds us of the fact that we cannot always rely upon the apparent success of any treatment.

507 Franklin Street, Philadelphia.

NOTES ON RECENT PROGRESS IN PHYSIOLOGY AND PATHOLOGY IN PARIS.

(Continued from page 348.)

M. PASTEUR'S METHOD OF PROPHYLAXIS AGAINST HYDROPHOBIA.

M. PASTEUR, at a recent meeting of the Académie des Sciences, stated that, after innumerable experiments, he had arrived at a prophylactic method which rendered animals exempt from rabies,—one so prompt and practical that he does not hesitate to apply it to animals in general, the human race included. A rabbit, after trephining, is inoculated under the dura mater from the spinal marrow of a rabid dog; the rabbit becomes rabid after fifteen days' incubation. A second rabbit is inoculated from the first, a third from the second, and so on through a successive series. A tendency to present a shorter time of incubation is soon exhibited. After twenty or twenty-five successive inoculations, the period of incubation is reduced to eight days, which continues through a further successive series of twenty inoculations, and the incubation-period is then reduced to seven days, which continues through a further series up to the ninetieth inoculation. M. Pasteur has arrived at this number of successive inoculations, and there is a very slight tendency to exhibit an incubation-period of less than seven days.

These experiments were begun in 1882, and have been carried on during three years without the series having been once interrupted or any virus used that was not

taken from a successive series of rabbits dead from rabies: thus it was always pure and possessed identical properties. This, says M. Pasteur, is the *nœud pratique*, the secret, of the method. The spinal cords of these rabbits are rabid throughout. If a small fragment be detached from these cords and suspended in dry air, the virulence gradually disappears. The length of time necessary for its final disappearance depends on the thickness of the fragment and the surrounding temperature: the lower the temperature, the longer the virulence lasts. When the rabid spinal marrow is placed in carbonic acid gas, the virulence lasts during several months, always provided it is preserved from contact with foreign microbes.

In order to render a dog refractory to rabies in a comparatively short time, M. Pasteur adopts the following method. A series of bottles containing dry air are made ready by placing in each a piece of potash. Every day a fragment of a spinal marrow from a rabbit recently dead from rabies, after seven days' incubation, is placed in one of these bottles; every day a dog is inoculated under the skin with a Pravaz syringe full of sterilized broth, in which a fragment of one of these dried cords is mixed. The first inoculation is made with a fragment prepared several days before the inoculation is made, in order to be sure that it has lost its virulence. The following inoculations are made with preparations more recently prepared. The last used is of one or two days' date. The dog thus treated is incapable of contracting rabies.

M. Pasteur had arrived at this stage of his experiments when a child was brought to his laboratory badly bitten by a mad dog. Sixty hours afterwards he was inoculated under the skin of the right side with a Pravaz syringe half full of marrow removed from a rabid rabbit, which had been exposed to dry air during fifteen days. On the succeeding days the inoculations were made in the following order:

July 7	9 A.M.	Marrow of	14 days.
" 7	6 P.M.	" "	12 "
" 8	9 A.M.	" "	11 "
" 8	6 P.M.	" "	9 "
" 9	11 A.M.	" "	8 "
" 10	"	" "	7 "
" 11	"	" "	6 "
" 12	"	" "	5 "
" 13	"	" "	4 "
" 14	"	" "	3 "
July 15	11 A.M.	Marrow of	2 days.
" 16	"	" "	1 day.

Thirteen inoculations were made, the treatment lasting ten days. Joseph Meister, the child in question, is in perfect health at the present time.

M. Pasteur does not believe that the progressive attenuation of the virus of the spinal cords exposed to dry air results from the contact with this air: he believes it to be more probable that the microbes the cause of rabies produce during their artificial cultivation a substance hostile to their own development. Data already in existence concerning the *modus vivendi* of these organisms support this hypothesis. M. Pasteur at a future period will publish further details. He urges that an establishment should be organized where rabbits might always be kept inoculated with the disease. A never-failing supply of spinal cords of both old and recent inoculation would thus be furnished.

M. Pasteur was present at a recent meeting of the Conseil d'Hygiène, when M. Léon Colon, in the name of the Council, made a short eulogistic speech, which M. Pasteur acknowledged. He stated that, since Meister was treated, every day people bitten by mad dogs had appeared at his laboratory to be treated in the same way. M. Pasteur considers that an establishment for the sole treatment of hydrophobia is indispensable. The expense would not be great, but his system must be further tested, in order that a number of successfully-treated cases may warrant the organization of such an establishment. M. Dujardin-Beaumetz said he had noted sixteen cases of hydrophobia since last January. The last death was caused by a dog which had previously bitten four other people. M. Brouardel asked if inoculations made a month or six weeks after the bite had been inflicted would be efficacious. M. Pasteur said he believed he could answer in the affirmative, although he had not absolute experimental proof. He had just received a telegram from Algiers, telling him that three children had been bitten by a mad dog; one died on November 5. He was asked if he would treat the two others: he had replied in the affirmative. M. Pasteur hopes to save both of the remaining children; but, if one dies, it will be easy to determine which virus is the cause of death. In rabbits, hydrophobia occurs on the fif-

teenth day when the inoculation is made with the virus of a mad dog; on the seventh, when with the virus of preventive inoculation. M. Pasteur has sixty people under treatment for bites from mad dogs, who have come from all parts of the world since he made his remarkable communication to the Académie des Sciences. We are authorized to state that M. Pasteur will receive for treatment all people who have unfortunately been bitten by a mad dog.

M. Pasteur has forwarded a letter of thanks to the Municipal Council of Havre for one thousand francs forwarded to pay a part of the expenses involved by his researches on hydrophobia. He informed the Council that he intended to devote it to paying the expenses of indigent poor who require treatment after having been bitten.

Dr. Tachard, of Columbia, contributes to the last number (November 8) of the *Union Médicale* the history of a case of hydrophobia especially interesting at the present moment, when the whole scientific world in France and other countries is following with intense interest the result of M. Pasteur's inoculations. Dr. Tachard was called in to treat a young man, 25 years of age, living in Columbia, who complained of a spreading pain in the right arm, which he believed was owing to overexertion at the gymnasium. The pain increased, and he was unable to swallow any fluid: he was horrified at the proposal of plunging his hands into cold water. After a searching inquiry, Dr. Tachard learned that eighteen months ago the patient had been slightly bitten on the right hand. Dr. Tachard immediately communicated with M. Pasteur, who regretted that he was powerless to relieve the sufferer. He said "he could save, but not cure."

ALCOHOLISM IN ITS MEDICAL AND LEGAL ASPECTS.

The question of alcoholism in all its bearings is second only in interest at the present moment to the one of hydrophobia. It evidently has not the same scientific interest, and could not offer a field of research to a Pasteur; but its chemical and medical aspects are of great social importance, and have attracted the attention of a great many of the leading men. Dr. Lunier, the distinguished authority for mental diseases and indefatigable hygienist, for fifteen years carried on warfare against the growing tendency to alcoholism in France. A few weeks before his death he published an interesting memoir on the subject of vintage and public health. He discussed the subject at a meeting of the Académie de Médecine, and stated that wines from the south of France can neither be kept nor imported unless alcohol be added to them: if the proportion do not exceed three per cent. there is not any danger to public health. The strength of the alcohol must be limited to twelve degrees. Moreover, it is important that the alcohol should be added when the wine is in vats, before the second fermentation takes place. If this precaution be not observed, the result will be a simple mixture instead of an alcoholic wine,—an alcohol weakened by the presence of wine, and very injurious to the health. It is imperative that vinous alcohol be used. Manufactured alcohol, extracted from beet-root or potatoes, especially if added to wine in casks, is excessively injurious.

M. Girard, the *chef* at the Paris Municipal Laboratory, read, at a recent meeting of the Société de Médecine publique et d'Hygiène, a note on the falsification of alcohol and the necessity of instituting a strict investigation concerning the influence of falsified alcohol on the increase of insanity. Alcohols have toxic properties, which increase with their atomic weight. Brandy would be dangerous if it contained alcohol belonging to a higher series than ethylic alcohol. Brandy, cognac, etc., are manufactured: the aroma is given to them by using an article of German manufacture, which is considered injurious to health. The essential oil of lees of wine is obtained from Germany, and is invariably used in manufactured alcohols.

M. Moltet, a well-known physician whose specialty is mental diseases, has read a most interesting paper before the Académie de Médecine on the responsibility of criminal drunkards. Crimes, murders, etc., committed when the perpetrators are under the influence of alcohol are much on the increase in France. Alcoholism at the present time presents unusual characteristics. M. Moltet believes that MM. Dujardin-Beaumetz's and Audige's researches explain this. Manufactured spirits currently sold are more toxic than pure vinous alcohols: they contain empyreumatic sub-

stances which exercise a most dangerous influence on the nervous system. This is manifested by sudden fits of frenzy and savage, brutal impulses. Magistrates are at a loss how to judge a criminal who suddenly commits a crime without any reason or previous intention. If there had been previously momentary delirium from a cerebral lesion of alcoholic origin, the medical expert's evidence would give some clue; but after the momentary influence of these manufactured spirits has passed away the drunkard is in a normal condition, and no symptom can be detected suggesting the probability of a return of mad impulses. M. Moltet cited a curious instance of the questionable responsibility of a murderer. An Italian, who always worked in compressed air and was of excessively sober habits, allowed himself to be overpersuaded by his companions and drank large quantities of alcoholic liquor. About twelve o'clock at night he was alone in the streets, trying to find his home, when suddenly, without the slightest provocation, he drew his knife and stabbed several people at the corner of a street. One among them died from the wounds inflicted by the Italian. The murderer was with difficulty captured. As soon as he reached the station-house he fell into a profound sleep. The next morning, when questioned, he did not deny the crime imputed to him, but said, if true, he had no idea how it happened. Working in compressed air induces neuralgia, nervous disturbance, and in some cases produces a general cerebral condition which increases alcoholic susceptibility. The jury disregarded these considerations, but the final judgment took them into consideration, and a less severe sentence was passed than would have been otherwise given.

Still more recently, M. Lancereaux, professor agrégé at the Paris Medical Faculty and hospital physician, read statistics concerning alcoholism before the Académie de Médecine, which he had collected in hospitals in the interval from 1860 to 1875, a period of fifteen years. They show that the patients addicted to excessive drinking admitted into hospitals are mostly people from the provinces, where pure brandy is largely consumed. M. Lancereaux classes alcoholic drinks under three headings: cider and beer; wine and wine-brandy; brandy extracted from cereals, potatoes, and liquors made from different extracted principles. Cider, according to M. Lancereaux, is a healthy drink: even when it is indulged in to excess, it produces only transitory intoxication, free from any pathological sequelæ. The consumption of beer is greatly on the increase, and M. Lancereaux says that this is not to be regretted. Beer is not an unhealthy drink: it encourages obesity and slight gastric disturbance, but does not produce any more serious troubles. Wine contains more alcohol and produces various ill effects: there is rapid stimulation of the nervous system, and the excess absorbed determines organic lesions of the nerve-centres and liver. Alcoholism resulting from over-indulgence in wine, according to M. Lancereaux, is favorable to the development of tuberculous meningitis. He has had several opportunities of observing this disease in very young children to whom wine was habitually given. Children of vinous drunkards do not inherit the vice, but this misfortune overtakes children whose parents indulge in drinks manufactured from cereals and potatoes. These drinks determine cerebral and vasomotor disturbance, and impair the intellectual faculties; succeeding generations degenerate, and acute diseases under such circumstances become intensified. Liquors manufactured with these alcohols and different essences determine similar conditions, and especially an exaggerated excitability of the sole of the foot and on each side of the body where the nerves emerge. The descendants of these drunkards have an unconquerable craving for alcohol; they are frequently idiots, and after the second or third generation they become shorter in stature. Rigorous investigations made in France and Switzerland, where these manufactured alcoholic drinks are most largely consumed, demonstrate the accuracy of these details. M. Lancereaux said that the government will be guilty of a grave fault if it does not legislate for the present state of things with regard to alcoholism. In a country where manhood suffrage exists, the enforcement of regulations to prevent alcoholism is always neglected. M. Lancereaux suggests that all drinks that are harmless or only slightly dangerous should be allowed to be sold without restraint, provided they are not falsified and are of good quality. Under this class he includes cider, wine, and beer. He also suggests that the manu-

facture of cognac from cereals, beet-root, and potatoes should be under strict superintendence; that rewards should be given for the discovery of means of improving these liquors, either by removing from them injurious substances or by transforming them into others less dangerous and thus rendering their effects similar to those of vinous alcohols. He also desires that brandy should be burdened by a heavy tax, according to the place where it is sold; that the sale of this drink should be limited; that the sellers should be liable to severe rules and penalties; and that only those who are well known for their good conduct should be granted a license. All responsible drunkards, according to M. Lancereaux's code, should be punished. Houses of refuge should be provided for those who cannot control their habits.

Dr. Oettingen, who was formerly Dr. Lancereaux's house-surgeon, has chosen for the subject of his doctoral thesis "Alcoholic Paralysis." This form of paralysis, according to Dr. Oettingen, is not of central origin, but peripheral, and results from diffused neuritis. Alcoholic paralysis is always preceded by a series of symptoms clearly indicative of alcoholism, and it is accompanied almost always by phenomena special to this form of paralysis: namely, acute pain in the limbs, pricking sensations, and paresis, which is most intense on waking, and is generally the forerunner of paralysis. The extensor muscles of the toes are paralyzed first, and the foot resembles a case of talipes. This form of paralysis sometimes steals on slowly, at other times rapidly, and becomes generalized. Facial paralysis never occurs, and deglutition is rarely affected. The bladder and intestines preserve their normal condition; neither is there paralysis of the muscles of the eye. Clinically speaking, there are three different forms. The first consists of paresis easily cured; the second is chronic paralysis, and may continue for months and years; the third progresses rapidly, and is generally fatal after a few months. The general health becomes seriously deteriorated, the tongue is dry, incurable diarrhœa sets in with frequent sickness, and eschars appear on the sacrum. Generally, muscular atrophy accompanies alcoholic paralysis; but other trophic and vaso-motor disturbances have been observed. The pain is best combated by electricity.

THE ETIOLOGY OF PULMONARY TUBERCULOSIS.

M. Thaon, of Nice, at a recent meeting of the Paris Biological Society, read a paper on the initial lesions of pulmonary tuberculosis. The author has examined a considerable number of pathological specimens taken from different animals which had died from experimental subacute tuberculosis or chronic tuberculosis according to the will of the experimenter. Guinea-pigs fed morning and evening on tuberculous sputa, powdered and mixed with sterilized water, invariably died on the twelfth or fourteenth day. The lungs were a solid, compact mass of a reddish-brown color, covered with yellow spots. On a histological examination, it was observed that the tissues presented small separated areas of lobular pneumonia, measuring about one-third of a millimetre. Treated with picro-carmine they became colored a deep red. They consisted of closely-packed cells undergoing proliferation free from degeneration, and were lodged in the beginning of branching bronchial tubes. Similar lesions were observed in the pulmonary alveoli; and these miliary masses were also grouped round the pulmonary vessels. Bacilli were present in considerable numbers in the areas of miliary pneumonia; in those of catarrhal pneumonia they were less abundant. Bacilli could be observed migrating from the bronchi into the alveoli. There they provoked proliferation of the pulmonary epithelium and its subsequent degeneration. Giant-cells, zones of epithelial cells, which formerly were recognized as the characteristics of tuberculous generations, also the various fibrous transformation special to pulmonary phthisis, were only observed in organs far advanced in tuberculosis. The bacillus, M. Thaon says, is the agent which produces all these changes. It is seen in the centre of the cellular elements in the giant-cells, and does not disappear until the caseous masses become one uniform vitreous mass.

At a subsequent meeting M. Thaon showed a series of illustrations of the lesions characteristic of infectious diphtheritic broncho-pneumonia, of measles, and whooping-cough. It was evident that the effusions consisted solely of microbes in pus-cells and in large degenerated pulmonary cells. M. Thaon found in the lungs the two varieties of microbes described by

Loefler in diphtheritis, zooglœa and bacilli, but disagrees with Herr Loefler in considering the bacilli the important factors. The zooglœa are present from the onset of the lesions; the bacilli appear later on at the extremity of the bronchi in areas of long-standing lesion. The broncho-pneumonia of measles and whooping-cough is different from that of diphtheria. At the onset small isolated nodules appear. They are as fine as tubercular granulations, and are formed by acinous pneumonia and round elements. They resemble leucocytes pressed one against the other. Treated with carmine they take a deep-red coloration. If these nodules be examined, it will be seen that the intra-alveolar cells are filled with round microbes at the diplococcus stage, and with chains consisting of three, five, and seven seed-like bodies. These microbes are larger than those of the zooglœa of diphtheritis. The alveolar cells which contain them assume a vitreous aspect as soon as the microbes exceed a certain number. Besides these round parasites, layers of bacilli of a uniform length are observed on the surface of the different bronchi and in those alveoli which are in an advanced pathological condition.

BRONCHO-PNEUMONIA IN THE COURSE OF INFECTIOUS DISEASES.

M. Thaon eloquently urged that hospitals for children's infectious diseases should be built. Measles and whooping-cough increase the mortality in hospitals to a considerable degree, whereas in private houses, where the patients are not in contact with air impregnated with microbes, they are relatively harmless. The isolated pavilions organized in 1882 have not been sufficiently effective. The mortality in them is five in six, and broncho-pneumonia always precedes death,—that is to say, all the fatal cases were due to this complication.

M. Darier published last March his doctoral thesis on "Broncho-Pneumonia in Diphtheritis," and at one of the last meetings of the Biological Society he communicated the results of his subsequent researches on that subject. The micrococci which he described in his thesis under two aspects—as round bodies grouped together like diplococci, also often in long, sinuous chains, and sometimes arranged in closely-packed groups and cloudy masses—have been observed by Dr. Darier to indicate by these different dispositions micro-organisms of different species. This author, by artificial cultivation, has succeeded in isolating four different species of micro-organisms. Evidently, minute care was necessary in order to avoid the presence of bacilli of putrefaction. The species isolated by M. Darier were the staphylococcus pyogenis aureus, the staphylococcus albus (or a micro-organism which closely resembles it), the streptococcus pyogenis, and, finally, the bacillus of diphtheria. This latter he met with nine times out of thirteen. The first three species are easily cultivated in veal-broth, by gelatin, or agar-agar is added. The last species named is only cultivated on gelatinized serum.

M. Darier concludes, from the results of this series of carefully-made experiments with these isolated micro-organisms (staphylococcus aureus albus and streptococcus pyogenis), that they have a pyogenic action, and by their presence complicate primary pathological conditions; they intensify pulmonary inflammation already provoked by the bacillus of diphtheria, and induce blood-poisoning; they are capable of producing pulmonary suppuration. It seems probable that M. Darier has discovered a general pathological principle which may be expressed thus: When a pathogenic microbe penetrates into the human organism, it opens the door to many other micro-organisms which contribute their influence to that exercised by the specific microbe.

EXTRA-CARDIAC BRUITS.

M. F. Franck, who now replaces M. Marey at the Collége de France in the professorial chair, made an interesting communication at a recent meeting of the Biological Society on "Bruits gastriques rhythmées avec le cœur dans un cas de dilatation de l'estomac avec adhérence probable du péricarde" (gastric bruits synchronous with the heart-beats in dilatation of the stomach, with probable adhesion of the pericardium). Since Laennec, several clinicians have recorded metallic cardiac bruits in cases of dilatation of the stomach. Skoda, Dechambre, Gerhardt, Leichtenstern, etc., mention several instances of this kind. Korczynski adds to the number in clinical notes published in 1879, in the *Wiener Medic. Presse* (No. 47). M. François Franck has also observed them, but the subject of his communication to the Biological Society differed in some important respects from the phenomena previously met with. The patient did not pre-

sent a resonant metallic bruit resulting from an exaggeration of the valvular sound, in consequence of the stomach being dilated and filled with gases, but a gurgling systolic bruit (un bruit de gargouille systolique), similar to that when a thick fluid is beaten up. The bruit was at its maximum in the epigastric region, but was heard at a distance. There are two hypotheses to explain these extra-cardiac bruits of gastric origin. The first supposes that at each systole the heart contracts abruptly, and the heart, stomach, or lungs receive a shock; the second believes that the bruit is the result of the contraction of the ventricles when they empty their contents. This theory coincides with M. Potain's exposition of the clinical aspect of the question. He showed that these bruits are not systolic, but meso-systolic, appearing at the same moment that the ventricles empty themselves. The extra-cardiac bruits of gastric origin are owing to dilated stomach or to its walls being flaccid, or to an accumulation of fluid or gases in an organ. In addition to these causes, it is possible that violent systolic contraction of the heart may also enter into the question. Adhesion of the pericardium always increases the violence of systolic contraction. Extra-cardiac bruits, with contraction of the epigastric surface synchronous with the cardiac pulsation and exaggeration of the normal jugular pulse, may be considered as symptoms that indicate with unfailing certainty cardiac symphysia.

In the case of M. Franck's patient, when the stomach was emptied of its gases and of its other contents the bruit disappeared almost entirely. The patient, who was previously much inconvenienced by its presence, was the first to announce its departure, but on auscultation traces of the bruit were detected. It was reproduced when Vichy water was introduced into the stomach, but the gurgling characteristic was absent: this was probably due to the absence of viscosity in the contents of the stomach, and its abundance when the bruit de gargouillement was heard.

DECLINE IN THE CONSUMPTION OF ALCOHOLIC DRINKS.—The report of the Internal Revenue Department shows for the year ending last June a decline of nine millions in taxes as compared with the year before, showing a greatly diminished consumption of alcoholic liquors in this country.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY HOSPITAL.

SERVICE OF D. HAYES AGNEW, M.D.,

Professor of Surgery in the University of Pennsylvania, etc.

(Reported by CHARLES BAUM, M.D.)

REMARKS ON WOUNDS OF THE HAND.

GENTLEMEN,—This patient has just been admitted to the hospital. He has been employed at sawing wood, and the soft parts of the middle finger of the right hand have been injured by a circular saw. They are badly lacerated and stripped from the bones, which are much comminuted. The soft parts on the inner aspect of the index-finger are also lacerated, but the bones are not fractured or exposed. Much dirt and tar have been ground into the wound, making any attempt at repair tedious and necessarily accompanied by sloughing.

Wounds of the hand are so frequently encountered that every practitioner should know the anatomy of the part, in order to treat them with success. The hand is complex in its construction, and no injury to it should be dismissed without careful scrutiny. In it terminate the branches of three good-sized arterial trunks, having intimate anastomoses with each other; to it the nerves are very richly supplied; and here, too, the insertions of thirty-six muscles are made, all resting upon a skeleton consisting of some twenty-seven small bones, with curiously but properly constructed articulations, well adapted to combine strength and free motion, and possessing also a large surface of synovial membrane.

In the treatment of wounds of the hand, the first indication is to arrest hemorrhage, which may be accomplished in many cases by approximating the edges of the wound if it be made by a sharp instrument. Bleeding from the digital arteries can usually be arrested by properly-applied compression or by torsion of the vessel. When the palmar arches are divided, the wound should be enlarged if necessary, and both extremities of the bleeding vessel secured by ligature. If only one point is tied, the free inosculation of the vessels will soon cause fresh blood to flow from the wound. After securing the points, it may become necessary at times, as when the coats of the vessel are unsound, to limit

the blood-supply by applying oblong compresses over the radial and ulnar arteries, or to elevate the limb and flex the elbow at an acute angle.

The maximum vital energy of the upper extremity is attained in the hand: therefore, in the treatment of lacerated wounds of this member, after the arrest of hemorrhage and the removal of foreign bodies, the parts should be carefully examined, so as not to remove any portion which may show a sign of vitality. No one factor in the treatment of such wounds can be of such value as irrigation. When first applied, the water should not be too cool, for fear of lowering the temperature of the blood below that degree necessary to separate damaged fragments of tissue and secure repair.

Deep-seated abscesses frequently follow contused, punctured, and poisoned wounds of the hand. They are extremely painful, and are accompanied by rigors, fever, headache, restlessness, and loss of appetite. Unless promptly and properly treated, a stiff, distorted, and somewhat useless hand will result from disorganization of structures. These abscesses form in four localities: first, in the subcutaneous tissues, where they are least harmful, and may readily come to the surface; second, under the middle portion of the fascia, which corresponds to the hollow of the hand; third, beneath the thin expansion of this fascia, which covers the muscles forming the ball of the fingers; and, fourth, under a similar extension of the fascia spread over the muscles of the ball of the thumb. Any collection of pus in the middle portion of the fascia is most dangerous to the usefulness of the hand, owing to the strength of the aponeurosis and its connections with the two middle metacarpal bones. In such cases the swelling is frequently forced up between the metacarpal bones and appears on the dorsum of the hand, and also along the forearm, by being pushed beyond the annular ligament,—thus at times misleading the attending physician.

Palmar abscesses should be evacuated by early incision. In order not to wound the blood-vessels, it should be remembered that the lowest point of the superficial palmar arch corresponds to a line drawn directly across the hand, starting at the junction of the tissues of the thumb and index-finger and ending at the ulnar border. The digital arteries lie opposite the interosseous spaces and divide at the interdigital clefts, sending branches along the sides of the fingers. It is apparent, therefore, that incisions made along the middle of the fingers and metacarpal bones may be carried as high as the transverse line with safety. After dividing the superficial structures, the palmar fascia should be nicked and raised upon a director before opening it more freely. When a palmar splint is used, in all cases of injury of the hand, the padding should be adjusted to allow slight flexion of the fingers.

As the patient is ready, I will dissect the soft tissues from the middle finger and disarticulate at the metacarpo-phalangeal joint; then I will utilize the flap from the dorsal surface of this finger to cover the lacerated inner aspect of the index-finger as far as it will reach: thus doing somewhat of a plastic operation. Although the parts have been well washed with a solution of bichloride of mercury (1 to 1000), it has been impossible to remove all the tar which adheres to some of the fragments. I prefer to allow nature to throw off what cannot be used, instead of sacrificing any likely portion of the tissues. Iodoform will be dusted over the wound, which will be further dressed with lint moistened with carbolized oil.

NECROSIS OF TIBIA, WITH REMARKS.

This colored man is 30 years of age. About twelve years ago he fell and sustained a fracture at the lower fourth of the left tibia. Shortly afterwards an abscess formed over the seat of injury and discharged for several months, after which time a small portion of bone came away, when the wound closed, leaving a depressed cicatrix. Several months ago he received a severe contusion over the seat of the old injury, resulting in inflammation of the periosteum, which extended to the deeper structures and terminated in necrosis of the bone.

It must be remembered that the bones are subject to the same morbid processes as those occurring in the soft tissues, being modified somewhat in the former by the inorganic salts entering into their composition. At present I will confine myself to the results of inflammation upon the osseous system.

Inflammation in a bone passes through the same stages of determination, conges-

tion, and transudation as inflammation in the soft tissues. Any one or all of the structures composing a bone may be invaded. Although the external investing membrane, the bone-structure proper, and the lining of the medullary canal can be separated, yet there is such a close vital connection or continuity between them that disease beginning in one of the three layers may readily extend to the others.

If the inflammation involve the external investing membrane, or periosteum, alone, the process is termed *periostitis;* if the bone-structure proper, *osteitis;* if the lining membrane of the medullary canal, *endosteitis;* and if the medullary lining and the surrounding bone, *osteomyelitis.*

Periostitis may be produced by both local and constitutional causes. Blows, fractures, and gunshot-wounds are the most common of the former; scrofula, syphilis, gout, and rheumatism, of the latter. When inflammation begins in the periosteum, it is rarely confined there, but a portion of the osseous structure is involved, causing an osteitis, and the process may extend, producing osteomyelitis by implicating the medullary canal. Pain in periostitis is usually intensified at night, after becoming warm in bed. The swelling in the circumscribed variety is round in form, not abruptly defined, but fades into the tissues. At the onset redness is not pronouncedly marked. In some cases all the symptoms pursue a very acute course. When of constitutional origin, the symptoms belonging to the particular disease producing it will be present in addition.

The inflammatory lymph and leucocytes thrown out may undergo, first, absorption; secondly, ossification; and, thirdly, pus may form, causing partial death of the underlying bone, and leaving a bone-ulcer to heal by granulation. The flake of bone which is then thrown off is called an exfoliation. This occurs most frequently in children, and may follow a severe contusion which excited inflammation.

Diffuse periostitis usually occurs in persons under twenty-five years of age, often being very formidable and rapid in its course. The limb becomes swollen and painful, finally red, pitting on pressure, exceedingly sensitive and helpless. Rigors and fever usher in or accompany the process. Suppuration finally occurs, and may involve the entire periosteum of the bone, separating the diaphysis from the epiphysis, beyond which the disease rarely extends.

In *osteitis* the same causes are active as those in periostitis. At the onset the symptoms also are similar; but persistence of deep-seated, boring pains and long-continued alternations of improvement and relapse will indicate bone-inflammation. If the disease progresses, caries or ulceration occurs, with thickening around the bone, while the tissues are infiltrated with inflammatory deposits. Finally, a film of bone is exfoliated, an abscess forming to discharge it. At this stage a probe will detect either a movable fragment or come in contact with an irregularly-roughened, exposed bone. The ulcer which remains may undergo changes similar to an ulcer in the soft parts,—may heal, extend in width and depth, remain indolent, or fill up with granulation-tissue, which may extrude from the sinus in the tissues, and then is commonly called "proud flesh." In Pott's disease of the spine, caries often undergoes repair without producing an external opening.

Caries spreads most rapidly in bones having many cancelli: therefore the carpus, tarsus, vertebral column, and articulating ends of the long bones are most frequently involved. In favorable cases the extension of caries is limited by an inflammatory infiltrate which fills up the cancellated tissue of the surrounding sound bone, thus preventing an advance and at the same time favoring the separation of the diseased particles. Rarely does inflammation, when fully established in bone, end in resolution. Diffuse suppuration and abscess also may follow osteitis.

Endosteitis and *osteomyelitis* usually go hand in hand, and mostly result from gunshot-wounds, amputations, and fractures. A vitiated atmosphere, as in many large hospitals, is conducive to their development. In many respects the process resembles hospital gangrene. When the affection occurs in military practice, termination by resolution cannot be expected, owing to the great shock to the bone resulting from the injury and the unfavorable hygienic surroundings.

Very often it is difficult to recognize osteomyelitis. If deep-seated pain, great uneasiness in the limb when it is moved, and œdematous swelling with prolonged

suppuration follow an injury to a bone, the disease may have developed. In addition to these signs, the diagnosis is rendered more certain if the soft parts have separated from the bone and there is marked loss of strength, with rigors and fever.

Some of the symptoms of periostitis and endosteitis are similar, but when closely observed it will be found that the pain in the former is local and is increased by the slightest touch; in the latter the pain is diffuse and requires somewhat firm pressure to increase it. In the former, the swelling accompanies the pain at the onset of the disease; in the latter, pain will continue a long time without any visible swelling. In periostitis knotty and irregular deposits are liable to occur upon the bone.

Necrosis of the affected bone and death from pyæmia are apt to follow osteomyelitis.

We now come to consider necrosis, that for which our patient has applied for treatment. When first employed, the term necrosis was used to designate death of a bone, but recently the word has been extended in meaning to embrace death of any tissue. Necrosis and caries bear the same relation to each other that mortification and ulceration in the soft parts do, being the same in kind but of different degree, —the former meaning death of a tissue in a large mass, and the latter death by particles. The disease shows a marked preference for the shafts of the long and short bones, but the flat ones do not escape.

In my judgment, a very large proportion of all cases of idiopathic necrosis can be traced to a constitutional vice. Injuries also are factors in the causation. Children under fifteen years of age furnish a large number of such cases; in them the scrofulous diathesis is usually observed. With such a systemic vice, a slight injury, insufficient food, exposure to cold, suppressed perspiration, or any low fever may be sufficient to develop inflammation which will terminate in death of a portion of the bone. Match-makers and those exposed to the fumes of phosphorus are liable to a peculiar form of necrosis attacking the maxillæ, and termed "phosphor-necrosis."

Whenever the blood-supply is cut off from any portion of a bone, that portion must die. Dead bone is a foreign body, and to effect its separation a wall of increased blood-supply is raised; free transudation then occurs, which serves to prevent absorption of morbid matters and aids in separating the dead from the living portion. All the changes which produce the separation occur in the living bone. A detached scale of bone from the periphery is called an exfoliation. The cavity resulting from this loss is a bone-ulcer, which must heal by granulation, forming a depressed cicatrix at the seat of the disease.

If death of a portion of the deeper structure of a bone occurs, the same process is employed by nature to separate as that used in peripheral necrosis. In central necrosis the dead portion or sequestrum is surrounded by a sheath or involucrum of living bone.

A sequestrum presents a peculiar, smooth, porous, or worm-eaten surface, with jagged or spiculated edges. This irregular form is not due to the effects of pus, in which the sequestrum is bathed, as was formerly taught, but to the irregular proliferation of granulation-tissue separating the dead from the living bone. The same irregular appearance is noticed when a slough is separated from the soft parts. When a central necrosis is present, the osteogenic function of the periosteum becomes exceedingly active, and a deposit of bony matter or callus takes place on the outer surface, increasing until the shaft may become very greatly thickened. Where the periosteum is deficient, openings or cloacæ are formed to allow exit for the products of inflammation. As cloacæ are not present in all cases, the inflammatory products must have been removed by absorption.

The symptoms first manifested in necrosis are those of ordinary osteitis. After a variable period of suffering, if indurated swelling and abscesses in the soft parts follow, with persisting sinuses capped with unhealthy granulations, the doubt is removed. The condition will be verified if denuded bone can be touched by passing a probe along one of the fistulous tracts.

Great care must be exercised in giving a prognosis in cases of necrosis. In young, strong persons, if the disease is limited and not deeply situated, a favorable result may be expected. Necrosis of the femur is much more serious than that of the tibia, while necrosis of the cranial and pelvic bones is accompanied by still greater danger. Should the articulating portion

of a bone become invaded, the risk to limb and life is greatly enhanced. As the patient increases in age, as a rule, his chances for recovery decrease. During the course of necrosis of the cranial bones, meningitis and intracranial abscess may occur. Anchylosis and even the loss of a limb may result from a sequestrum entering or lying within a joint. In working its path to the surface a sequestrum has ulcerated through the walls of a large blood-vessel and induced fatal hemorrhage. Amyloid and fatty changes in the internal organs, especially the kidneys,—the so-called "surgical kidneys,"—may be induced by the prolonged suppuration; also pyæmia, erysipelas, and pulmonary tuberculosis are liable to develop during necrosis. In view of all these dangers, the surgeon should be watchful to operate at the first proper moment.

This brings us to consider the treatment of necrosis. Our first effort should be to limit the process of inflammation by elevating the limb, accompanied by local depletion, anodyne lotions, and poultices. Often a blister is followed by good results. Constitutional medication should not be overlooked, especially in cases of syphilitic and rheumatic origin, in which iodide of potassium and cod-liver oil are of great service. Any collection of pus should be liberated as soon as detected, thus avoiding much suffering, and in delicate subjects even danger to life. When the process is restricted to the external lamellæ of the bone, pain can be greatly relieved and the inflammation often limited by means of an early deep incision, laying open the periosteum in a line with the long axis of the bone.

The second point in treatment is the removal of the sequestrum. Suppuration and sinuses will continue as long as the dead bone remains; therefore it should be removed as early as possible. The rule for any cutting operation for this purpose is well established,—namely, do not operate until nature has separated the dead fragment. Many months, or even years, may elapse before the proper time comes. When an operation is attempted at too early a date, the inflammation which is excited as the result of minute fracturing of the bone may destroy a large extent of previously uninvolved bone.

In order to determine when the fragment is free, a director, which owing to its strength is better than a probe for this purpose, should be passed along a sinus, and by pressing upon the fragment its mobility can be determined. Should a sequestrum ulcerate into a main arterial trunk, amputation will afford the strongest hope of recovery; but should a smaller vessel be implicated, the parts must be freely laid open and the vessel tied at the point of injury.

In our patient the disease is limited and the thickening over the bone is not very great. There is one sinus, along which I now pass a director and readily detect a movable piece of bone. In order to prevent hemorrhage, an Esmarch's elastic bandage will be applied, thus making the operation almost bloodless. When such a roller is not at hand, and free bleeding is expected, a tourniquet should be applied over the main trunk supplying the limb. All incisions should be planned to avoid important nerves and blood-vessels. If two openings or cloacæ in close proximity are observed upon reaching the bone, it is proper to cut through the bridge between them by means of strong cutting-pliers; otherwise, with a chisel and mallet an opening is made through the ring of newly-formed bone and thus the sequestrum exposed. Owing to the irregularities of the living bone, it may be necessary to pry the dead portion out by means of a lever. If the sequestrum be too large to pass through the opening made in the involucrum, the former may be cut and be extracted in pieces. Before dressing the wound, a finger should be introduced into the cavity to search for any fragment of dead bone. If the walls feel velvety and soft, due to granulation-tissue, you can be assured all dead particles have been removed. The wound should then be washed thoroughly with mercuric chloride solution (one to two thousand), and packed with lint moistened with carbolized oil, thus preventing union of the soft parts and affording a channel of escape for any discharge which may result.

[The operation was successfully performed.]

NOTE.—The patient from whom Professor Agnew removed a papilloma of the bladder by perineal section—reported in the *Medical Times* of January 9—has returned to his home, without any remaining symptoms of discomfort.

TRANSLATIONS.

Experiments upon Protective Charbon-Vaccination in Russia.—The experiments on splenic-fever inoculations made in Dorpat by Prof. E. Semmer and his confrères, with both imported and original virus-cultures, had not been attended with success, and protective inoculation in Russia was considered a failure, until Prof. Zenkowski recently decided to investigate the subject anew in South Russia, where large flocks of sheep were placed at his disposition by their owners for the experiment. Having prepared his own virus, according to Pasteur's method, in the botanical laboratory of the University of Charkow, Zenkowski vaccinated, in the summer of 1885, about thirteen hundred and thirty-three sheep, with the following results: the loss after the first vaccination (with *premier vaccin*) amounted to from 1.55–1.6 per cent.; after the second (with *deuxième vaccin*) from 0.099–0.3 per cent.; or an average of 1.8–2.0 per cent.

In November, 1885, a commission officially appointed by various agricultural societies and representatives of the government selected thirty head from the previously-inoculated flock and submitted them to the test of inoculation with fresh charbon-virus, at the same time taking ten other sheep which had not been previously vaccinated for comparison. Within twenty to forty hours after the inoculation, eight head of the previously-unprotected sheep died, and on the sixth day the ninth succumbed to well-marked splenic fever; only one survived out of ten.

The thirty vaccinated sheep showed on the day following the trial a rise in temperature from 39.9° to 41.6° C.; but it fell on the fourth day to the normal, 39.5°. One of these sheep was worried to death by dogs, and another died of pleuro-pneumonia a few days after; no trace of anthrax-bacilli could be found in the blood or tissues of either.

These experiments of Zenkowski are of great importance to the sheep-raising interest of South Russia, where the frequent ravages of splenic fever have caused a loss of over twelve per cent. in a single year. These losses, it is claimed, can be reduced to from two to three per cent. by properly-conducted vaccination.—*Centralblatt für die Medizinischen Wissenschaften*, No. 1.

The Fate of Disease-Germs in the Organism.—Following the suggestion given by Metschinkoff, who showed that the intracellular digestive process exercises a very important function in destroying bacteria, Dr. Ribbert (*Deutsche Med. Wochenschrift*, No. 31) endeavored to determine more positively the exact means of its accomplishment. It had been ascertained that the bacteria speedily die when they become enveloped by protoplasm, and are, in fact, destroyed in large numbers by being included by the white corpuscles, because they are thus isolated from their nutritive materials (acids, etc.). This process was observed occurring in the interior of the liver, lungs, and spleen of rabbits after spores of mould-fungus had been introduced into the blood. In these animals, wandering cells quickly formed a zone around the masses of spores, and promptly led to their destruction. With regard to the rôle played by the kidneys, while it is true that all kinds of germs may find their way out of the body by this route, they are not only excretory organs for the parasites, but they also may increase and develop into inflammatory centres, and it is not improbable that the body may be again infected from these new centres.

The Zymotic Action of Certain Pathogenic Micro-Organisms.—M. Arloing, in a recent communication to the Académie des Sciences, stated that he has made experiments with four different kinds of virus,—blood from charbon (Toussaint), puerperal septicæmia, gangrenous septicæmia, bovine symptomatic charbon. The results are as follows: the anaërobic virus of gangrenous septicæmia of bovine emphysematous charbon (or charbon de Toussaint), when fresh, produces butyric fermentation in most of the fermentable sugars and in several neuter hydrocarbon substances. Almost the same results are obtained with virus recently dried; but when virus has been dried some time, or when their pathogenic activity is diminished by the action of heat, they lose their zymotic action, but retain nevertheless their dangerous properties: therefore the deduction follows that the pathogenic properties of virulent micro-organisms are in a degree separate from their zymotic properties. The latter disappear the first, which indicates that they are contained in the mycelium and not in the spores.

EDITORIAL.

ALCOHOLIC PARALYSIS.

AMONG the disorders of the nervous system which may follow the prolonged use of alcohol certain forms of paralysis occupy a prominent position, and of late we have obtained a considerable body of clinical and pathological evidence which has materially widened our conceptions of these affections.

Of recent papers on the subject those of Schultz (in the *Neurologisches Centralblatt*, 19–21, 1885) and of Dreschfeld (in *Brain*, January, 1886) are perhaps the most important. The latter gives an exceedingly interesting historical note, which shows that the credit of having first accurately described the condition must be attributed to James Jackson, of Harvard, in 1822, and, from the quotations given, we feel that Dr. Dreschfeld is most just in characterizing his communication as "a very succinct and at the same time very accurate and complete account of alcoholic paralysis."

Two forms may be recognized,—one with a preponderance of ataxic symptoms and very little paralysis, the other with marked paralysis and but slight ataxia. The ataxic form, spoken of by some writers as the "pseudo-tabes of alcoholics," is a milder type, and the similarity to ordinary locomotor ataxia may be very striking: indeed, the cases are not infrequently regarded as instances of this disease running a rapid course. There are the severe tearing pains, the uncertain gait, with the feet wide apart, and the absence of tendon reflexes. According to Schultz, the differential diagnosis lies in the relatively more acute course, in the earlier appearance of wasting of muscles, which is a late feature in genuine tabes, in the marked diminution of the electrical irritability, and in the absence of the Argyl-Robertson pupil, the girdle sensation, and the sphincter disturbances. In alcoholic cases there is almost invariably slight fever.

In the typical cases of alcoholic paralysis, loss of power, with wasting of the muscles, comes on either acutely or slowly, and affects chiefly the extensors of the fingers and toes. The patients often come under observation when unable to stand or walk, and it may be impossible to say whether there is a preliminary ataxic stage. Of this form, Ross, in his recent "Hand-Book of Nervous Diseases," gives an excellent description. The limitation of the paralysis to the extensors of the feet and hands is very peculiar, and there may be double wrist-drop, as in lead-palsy. Sensory disturbances are common, particularly tearing pains and cutaneous hyperæsthesia. Vaso-motor disorders are shown in the congested state of the extremities, to which Broadbent directed special attention, and there may be œdema. The tendon reflexes are abolished, but the cutaneous reflexes may be, according to Schultz, normal, though Ross and Dreschfeld speak of them as diminished or absent. The affected muscles usually show the reaction of degeneration. The disease seems more common in women than in men,—a point which Jackson noted.

Of eleven cases tabulated by Schultz, five died, four recovered, and two were improved. Of fifteen recent cases mentioned by Ross and Dreschfeld, three died, five recovered, and the others were under treatment.

The morbid anatomy of this disease has been carefully studied in five or six instances, and the lesion in each case was found to be a peripheral neuritis, without any affection of the spinal cord. There

can be very little doubt that the instances of peripheric nerve-tabes described by Dejérine and others, in which, with marked ataxic symptoms, the cord was found intact, were cases of alcoholic ataxia.

In addition to these forms, we may also recognize an alcoholic paraplegia, a condition referred to by many writers, notably Wilks, whose account, however, resembles in many respects that of James Jackson. The paralysis was not complete, and the cases come rather under the form we have already discussed. But there is a form of paraplegia in drunkards of which we have seen at least two examples, coming on suddenly and tending to complete loss of power, which may last for several days and then gradually disappear. Such cases are doubtless spinal, and not related to the incomplete paralysis dependent upon peripheral neuritis.

CONGENITAL DISPLACEMENT OF THE HIP-JOINT.

CASES of congenital displacement of the head of the femur are of comparatively rare occurrence. Perhaps this may be regarded as fortunate, since their treatment has not hitherto yielded brilliant results. Indeed, in those with marked deficiency in the development of the acetabulum, the best surgical authorities have agreed, almost without a dissenting voice, that palliative treatment is alone admissible. Heusner, in 1884, in a girl 20 years of age, performed an excision of the head and neck, with nearly an inch of the shaft of the left femur, and with a gouge deepened the acetabulum. In eleven weeks the patient was able to walk with the aid of a cane, and eventually made a satisfactory recovery. This case was reported to the meeting of the Deutscher Naturforscher und Aerzte in Magdeburg, when the novelty of the treatment—this being the first case which had been subjected to excision for congenital dislocation—and the successful issue attracted general attention.

A far better result, however, has been quite recently obtained by an American surgeon, Dr. Buckminster Brown, of Boston, without excision or other operative interference. In his case the patient was a female child 4 years of age, in whom there was double dislocation of both femurs and entire absence of cotyloid cavities. In the report of the case published in a monograph (also in the *Boston Medical and Surgical Journal*), four phototype illustrations admirably show the deformity and the application of the apparatus most ingeniously devised by the author, as well as the effects of the treatment. The child, in a period of a little over six months, and as a result of measures skilfully adapted to the conditions, was supplied with good, serviceable acetabula, in which the heads of the bones were permanently retained, even when the little patient resumed her walking exercise. The principle of treatment was to endeavor to secure by fixation and pressure a certain amount of absorption of the surface of the ilium in the normal site of the acetabula. This was accomplished by a simple form of apparatus for securing extension and counter-extension, position, and passive motion. During a portion of the time the child was, for several hours daily, placed in a prone position, with the thighs at right angles to the body and everted, in order to exert more pressure upon the ilium. The success obtained by this judicious and skilful treatment was most gratifying.

On the fourteenth day of January, 1884, the little girl was allowed to sit up in bed, for the first time in thirteen months, and experiments in locomotion with a wheel-chair were begun; six months later she walked with canes; and by January, 1885, she was able to walk without canes, but there was still present some evidence

of spinal debility. Displacement of the femurs had not taken place since March, 1883. The final note of May 25, 1885, stated that the child's walk was normal; she could step with natural firmness and vigor; she walked with ease, and, like other children, took especial pleasure in running.

We believe that this case marks a new departure in orthopædics, and both on account of the novelty of the measures employed and their skilful application do we feel warranted in thus directing the attention of our readers to what we must regard as a great achievement of American surgery.

THE RANK AND PAY OF HOSPITAL STEWARDS IN THE ARMY.

WE have been informed that efforts are being made to induce the present Congress to raise the grade and increase the pay of hospital stewards in the army.

A hospital steward's duties are to compound the medicines prescribed by the medical officer; to keep the records of cases; to make and record meteorological observations; to make out the routine medical reports of the post or hospital; to have immediate charge, under the surgeon, of the hospital and medical stores; and, in general, to act as clerk to the medical officer.

For these manifold and responsible duties, requiring for their proper performance a pharmaceutical education and no little executive ability, the hospital steward receives compensation at the rate of thirty dollars per month and the necessary allowances of clothing and rations. His rank is the same as that of the staff-sergeants of a regiment, and his only way of getting appointed to the position is by enlisting as a private soldier, after which he may or may not receive the appointment.

While we think that more care should be exercised than at present in selecting men for these positions, there can be no doubt that the pay is entirely inadequate and the rank of the steward absurdly out of relation with his duties and responsibilities.

We trust that the efforts for the improvement of the grade and pay of these men will be successful.

PROTECTIVE INOCULATION IN SMALLPOX AND RABIES.

IN the letter of Dr. Schultze published in our last issue, the comparison is instituted between the failure of inoculation for smallpox and the present public agitation of the question of the protective inoculation for rabies. Dr. Schultze calls our attention to the fact that the statement that "inoculation has been abandoned" should not be construed to mean that vaccination has been abandoned. He desires, however, to make the point clear that there can be no overlooking the fact that there are many people, intelligent in other things at least, if not in this, who doubt the efficacy of vaccination against smallpox, and there certainly will be far less opportunity for establishing the efficacy of such treatment (inoculation) in preventing the development of hydrophobia.

NOTES FROM SPECIAL CORRESPONDENTS.

BOSTON.

THE Obstetrical Society of Boston, the earliest organization of the sort in this country, has just completed the first quarter-centenary of its career, and celebrated the event January 5 by an elaborate banquet at Young's Hotel. The entire active membership of the Society, except four who were unavoidably detained, were present. The President, Dr. A. D. Sinclair, occupied the head of the table, and among the guests of the evening were Drs. Fordyce Barker, G. Kimball, of Lowell, and John Homans, of Boston. Letters of regret at unavoidable absence were read from many distinguished gynæcologists and

obstetricians, among the number being Drs. Goodell, of Philadelphia; Thomas, Emmet, and Lusk, of New York; Skene, of Brooklyn; H. P. C. Wilson, of Baltimore; W. S. Playfair, of London; A. R. Simpson, of Edinburgh; G. H. Kidd, of Dublin; and Litzmann, of Berlin. The speaking, much of which was of historical interest and value, comprised a fitting introduction by the President, a brief sketch of the history of the Society by Dr. B. E. Cotting, remarks on the deceased original members by Dr. G. H. Lyman, on the future of the Society by Dr. J. P. Reynolds, a response for the guests of the evening by Dr. Barker, and for gynæcology by Dr. John Homans. Dr. Kimball, of Lowell, one of the pioneers of ovariotomy in this country, also gave an account of some of his early operations.

Dr. Sinclair said, in his remarks, that the Society originated very shortly after the Obstetrical Societies of Berlin and of London, of which the former completed its quarter-century a few months ago, and the latter in February, 1884.

Dr. James H. Whittemore, the Superintendent of the Massachusetts General Hospital, died early in the year of a most painful affection from which he had been suffering for some two years. Patches of psoriasis on each of the hands took on a malignant epithelial character, and, the diagnosis being confirmed by eminent Continental surgeons whom he consulted, he submitted to an operation for the removal of one hand and portions of the other. This stayed the suffering for a time, but it returned with great severity, as the disease invaded successively many of the vital organs. Dr. Whittemore had served as assistant physician at the McLean Asylum for the Insane until his appointment to his superintendency, some nine years ago. His discharge of the duties of this position met with most unqualified approbation from all in any way connected with the hospital, and his heroism in the endurance of suffering excited universal admiration. He died at the early age of forty-six.

The Massachusetts Sewerage Commission, appointed nearly two years ago to investigate the methods of sewage-disposal best adapted to the various river-basins of the State, with a view to preventing the contamination of the water-supply of any municipality through the sewage of any other, has prepared a lengthy and exhaustive report to the Governor, in which it has availed itself abundantly of the best engineering skill. By maps and plans the solution of the problem is indicated for most of the towns and cities liable to infringe upon one another's inalienable rights to pure air and water. Comprehensive systems, adapted not to municipal boundaries, but to the physical conformation of the country, are favored, and the estimated total expense is apportioned equitably among the different cities and towns. Mr. Eliot C. Clarke was the advising engineer, and his and the Commission's work was revised by two consulting engineers, Messrs. Joseph P. Davis, of New York, and Rudolph Hering, of Philadelphia. Intermittent downward filtration is the method considered most efficient for depurating sewage, and is said to be capable of filtering ten times as much sewage as can be absorbed advantageously by any crop. Hence no attempt is made to secure profitable farming, but the prime motive is to filter as much sewage as possible. Broad sewage-irrigation, owing to the large area which it requires, is held to be impracticable; so also are the precipitation and depositing processes through the aid of lime, on account of the abundance of the sludge produced, which can neither be given away as a fertilizer nor discharged into a stream. In most of the large sewers required for Eastern Massachusetts, Boston is made to pay a portion of the expense on account of her great interest in the maintenance in a state of purity of her various sources of water-supply. These sources of supply are, unfortunately, so scattered that she must contribute to the drainage of several river-basins.

The vacancy in the chair of Obstetrics at the Harvard Medical School, caused by the resignation of Dr. J. P. Reynolds, has been filled by the appointment of Dr. W. L. Richardson, for some years assistant professor in that department, and visiting physician to the Massachusetts General and Boston Lying-In Hospitals.

Dr. W. B. Goldsmith, Superintendent of the Darwin Lunatic Asylum, the largest of our State hospitals for the insane, has been appointed Physician and Superintendent of the Butler Hospital for the Insane at Providence, Rhode Island, to succeed the late Dr. John W. Sawyer.

The first of a series of social gatherings of the members of the Medical Library Association took place at the Library Building January 15. On this occasion Mr. Cushing, the ethnologist, gave a description of the medical practice of the Zuñi Indians, as observed by him during his extended residence among that tribe. On a similar occasion in the near future a talk is promised by Dr. David Hunt on medical engravings, which will be illustrated by abundant specimens.

On the evening of January 29 an informal inspection of the new Nurses' Home in connection with the Boston City Hospital, of which some description has already appeared in your columns, was made by a number of ladies and gentlemen on the invitation of the Trustees. Some two hundred invitations had been issued, but the evening proved so inclement that many were unable to attend. Those who did so were apparently well pleased with the completeness of the arrangements for the health and comfort of the occupants. The library for the use of the nurses

has recently received a gift of five hundred dollars from Dr. Charles G. Weld, formerly a house-physician in the hospital, and a grandson of the late William F. Weld, of Philadelphia.

The Massachusetts General Hospital receives a legacy of ten thousand dollars from the estate of Mr. Henry P. Kidder, who died last week. C. F. W.

BOSTON, February 10, 1886.

BALTIMORE.

AT the last meeting of the Clinical Society, held on the 5th instant, Dr. Samuel Theobald read notes of a series of cataract operations by Von Graefe's method. In two of the cases Forster's method of hastening the ripening of the cataract was resorted to. One case reported presented the peculiarity of exceedingly rapid development. The patient, who was a shoemaker, had been able to work at his trade without any noticeable defect of vision up to a week before he applied for treatment, when the power of sight was entirely gone. In only one out of the seventeen cases reported did any bad results follow. In this case, although the operation was done without any untoward results, panophthalmitis followed, and the eye was finally enucleated. In most of the cases excellent vision was secured.

A paper on the latest therapeutic novelty, "Pneumatic Differentiation," was read by Dr. F. Donaldson, Jr. The immediate effects of treatment in the atmospheric cabinet are wonderfully favorable,—respiration becoming easier, cough diminishing, night-sweats disappearing, and the body-weight increasing. In his experience, Dr. Donaldson had not noticed any unfavorable effects.

Dr. I. E. Atkinson read an exhaustive paper upon the nature, frequency, prophylaxis, and treatment of scarlatinal nephritis. The various forms of inflammation of the kidney accompanying or following scarlet fever were thoroughly discussed, and their relations to the general disease considered. Dr. Atkinson considers the nephritic complication to be an essential part of the disease, and not an accidental sequel.

Dr. Whitfield Winsey read the notes of an extremely interesting case in which the patient had had adherent placenta, with hemorrhage, in eight out of eleven labors. In the last labor the patient succumbed to shock.

Dr. Moale exhibited a plaster cast showing the deformity resulting from a probable fracture through the internal condyle of the knee-joint. The patient had received no surgical attention at the time of the accident, and considerable deformity had resulted. The accident is an extremely rare one, only fifteen recorded cases being known to surgical authorities.

At another meeting of this Society recently, two cases of laparotomy for intestinal obstruction were reported by Drs. Frank West and Randolph Winslow. Both cases made a satisfactory recovery. The usual (apparently unavoidable) discussion on the value of antisepticism followed, in which the antisepticists seemed to have rather the advantage.

At the same meeting of the Society Dr. Clinton McSherry exhibited an interesting case of displacement of the heart to the left side, in consequence of retraction of the lung on that side. The apex-beat of the heart could be felt a little over two inches to the left of the left nipple, in the sixth intercostal space.

The pathological laboratory of the Johns Hopkins University is being rapidly put into a condition for practical work under the direction of Dr. William H. Welch, the Professor of Pathology. The laboratory is located in what is known as the autopsy building attached to the Johns Hopkins Hospital. The lower portion of the building will be used as an autopsy theatre, library, and possibly a city morgue, while the second floor is occupied by a museum, laboratories for the Professor of Pathology, his assistants, and students. The rooms are handsomely fitted up, and the apparatus is complete and of the most approved forms. Dr. Welch has just begun a course of lectures in the University on pathogenic micro-organisms. The lectures are delivered every Wednesday afternoon at five o'clock in Hopkins Hall.

The Medical and Chirurgical Faculty of Maryland is agitating the question of a medical law for this State. At a meeting held a few days ago a draft of a bill to be submitted to the Legislature was adopted, and a committee appointed, with instructions to advocate the passage of the bill before the Legislature. The bill is similar in its main features to that in force in Illinois, which has been so efficient in its working in that State.

The necessity of some law to regulate medical practice here is made evident by an incident which happened at the health-office in this city a short time ago. A female practitioner, who appends to her name the initials "M.D., V.D., C.M.S.," certified to the death of a patient under her charge. As she was not registered at the health department, as required by a city ordinance, she was sent for and informed of the necessity of registration and asked to show her diploma. She presented a diploma purporting to be issued by the "American Health College and Vitapathic Sanitarium." This the Health Commissioner declined to recognize, informing her that the institution was a fraudulent one. The "Doctor" then wrote to the president of her Alma Mater, stating that her diploma was refused recognition, whereupon she received a reply from which I give an interesting extract:

"Vitapathic Minister Physicians, who ad-

vertise and Practice Vitapathy in NAME *and* NATURE dont need to Register they are not M.D. Medical Doctors and Medical Boards and Medical Laws have nothing to do with them, Vitapathic Physicians dont have their Patients Die or if they did, or will die turn them over to some M.D. in time. *Our full Graduates* are Practicing in all the States with safety and success. We have fully Provided for all our Graduates to Practice *Vitapathy*."

The suggestion that "Vitapathic Physicians" should turn their patients over to some M.D. before the disease terminates fatally is almost as brilliant as the remark of the female partner of one of your Philadelphia irregulars, who testified some time ago that M.D. meant "Money Down," and not "Medical Doctor." G. H. R.

February 6, 1886.

PROCEEDINGS OF SOCIETIES.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, THURSDAY, JANUARY 7, 1886.

The President, B. F. BAER, M.D., in the chair.

DR. HOWARD A. KELLY exhibited recent specimens of pyosalpinx, hydrosalpinx, and papilloma of the hilum with gelatinoid thickening of the Fallopian tube. The histories of the cases will be given at some future time.

Dr. GOODELL stated that, while he recognized the necessity for operation in pyosalpinx, he did not think it necessary in hydrosalpinx. He now refuses to operate in some cases of cystic disease in which one ovary may contain a cyst as large as an orange, or in which the tube may be distended to the size of a sausage, because the sufferings of the patient and her general symptoms are not severe enough to warrant the operation. In many of these cases the symptoms may all be removed by the rest-treatment, and it should first be tried. Small cysts are frequently found in ovaries, especially when uterine fibroids are present, but they do not necessarily develop into large ones. In many cases the cause of pelvic symptoms can be diagnosticated by exclusion only, and, even when small cysts or dilated tubes can be felt, treatment should be first tried, and will be sometimes successful without operation. He thinks the error of the present time is in the direction of too much surgical interference.

Dr. MONTGOMERY remarked that there was a class of cases suffering from small ovarian cysts or distended tubes, in which the rest-treatment or any other loss of time could not be thought of, and in which operation seemed imperative. This was on account of the pecuniary condition of the patient, who may be self-supporting or who may be the only support of others. The suffering and exhaustion of the disease incapacitate them from work, relief is imperatively demanded, and he considered operation justified.

Dr. GOODELL recognized this element of poverty, and has operated for this reason in some instances. He was led to make his remarks by a case now under his care. A lady was sent to him for operation, after an opinion had been given by an experienced gynæcologist of another city that relief could be obtained by operation only. On one side the ovary was enlarged, and the other ovary was prolapsed and tender. Rest-treatment had wholly cured her. In these remarks he casts no reflection on any of Dr. Kelly's cases. Pus was present in all of them, and operation seemed to be demanded in all.

Dr. BAER has been strongly impressed lately with the views expressed this evening by Dr. Goodell. Dr. Baer thought all conservative means should be tried before operating.

Dr. KELLY replied that he had presented the specimens purely from an anatomical and pathological stand-point, and that he will give the histories at some future time, when the results of operation are well demonstrated. In each of them operation was imperatively demanded to save life. It is in such cases as those presented this evening that the great work in the future must largely lie. If the details of ovariotomy have been perfected, in such cases as these the chapter is only being opened. They are not examples of Battey's operation or Tait's operation, but stand as representatives of classes of disease well defined, with equally well defined indications for treatment. The extraordinary difficulty of digging such masses as these out of the pelvis makes operative interference very fatal, although it is the only resort.

Dr. WILLIAM GOODELL read a paper on

A YEAR'S WORK IN LAPAROTOMY.

During the past year he had had forty-four cases of laparotomy, with four deaths, as follows:

	Cases.	Deaths.	Recovery.
Ovariotomy . .	28	2	26
Oöphorectomy . .	9	1	8
Hysterectomy . .	2	1	1
Exploratory incision .	4	0	4
Pelvic abscess . .	1	0	1
Totals . .	44	4	40

Of these forty-four cases, twenty-five had been operated on at his private hospital, with two deaths; twelve were operated on at the hospital of the University of Pennsylvania, with one death; and seven were operated on at the homes of the patients, with one death.

Of these four deaths, one only was due to septicæmia, and that, a case of oöphorectomy, occurred in a private room of the hospital of the University. It was not, however, due to hospitalism, but to the adverse complications of the case. The ovary and oviduct were filled with pus and so matted by inflammation to adjacent structures that only a portion of them could be removed, and that in fragments. The pus unavoidably escaped into the peritoneal cavity, which was carefully cleansed and a drainage-tube put in; yet a fatal inflammation set in. Another death was due to shock after the removal of the womb containing a fibroid tumor with extensive adhesions and weighing seventeen pounds. The two deaths after ovariotomy were not due to septicæmia, and are somewhat mysterious. One case was operated on at the patient's home, in Bedford, Pennsylvania, and Dr. Goodell did not see her again. The cyst was parovarian, weighing forty-three pounds; was without an adhesion, and easily removed. The stitches in due time were removed, the bowels were opened, and everything did well for twelve days. Then obstinate vomiting set in, and the lady died on the seventeenth day. Six months previously she had had an analogous attack of vomiting, in which her life was despaired of. The fourth death took place from a supposed attack of malaria, to which the patient was liable. Both ovaries had been removed, the larger one weighing about thirty pounds. There were omental adhesions and very firm parietal ones, needing a number of ligatures. She recovered promptly from the operation. The wound united, the stitches were removed, and she was allowed to sit up out of bed. On the seventeenth day malarial fever with bilious vomiting set in, and she died rather suddenly on the twenty-first day, with symptoms of heart-clot.

Of the nine oöphorectomies, four were performed for ovaralgia, three for bleeding fibroid, one for epilepsy, and one for a menorrhagia which had resisted every known therapeutic measure.

In three cases of ovariotomy, all of them with papillary cysts, rupture had taken place a few hours before the operation, but although the peritoneum seemed thickened and injected no bad result followed. He considered papillary cyst to be benign in the very great majority of cases, and that the danger from the escape of ovarian fluid into the abdominal cavity was very much overrated. He had not refused to operate in a single instance of ovarian tumor, no matter how low the patient was or how firm were the adhesions. He had consequently had several exceedingly difficult operations. Out of his twenty-eight ovariotomies, there were twenty-one with adhesions. In four the adhesions were universal, in eight more they were intestinal, and in three they were uterine. This very large proportion of adhesions, when compared with those of European operators, he could explain only on the theory that physicians in this country have not yet been educated up to the idea of an early operation, and to a recognition of the evils of tapping. In the successful case of hysterectomy a tumor weighing eight pounds was removed, together with a portion of the enlarged womb. As the uterine cavity was not invaded, the large pedicle was transfixed, tied, and dropped. The four exploratory incisions were made with the view of removing the ovaries on account of fibroid tumors of the womb. But in each the tumor was so fixed by adhesions that the ovaries could not be reached, and the patients had previously stipulated that in that case the uterine growth was not to be removed. All did well. So also did a case of pelvic abscess communicating with the bladder and rectum. It was opened per vaginam by means of the abdominal incision, by which its exact position and size were determined.

With regard to the technique of the operation for laparotomy, Dr. Goodell stated that he used the ordinary knot and the Staffordshire knot indifferently; that he now, in the long incision, cuts directly through the umbilicus, instead of going around it on the left side; that he includes the recti muscles and all the tissues in the abdominal sutures; and that, while not a very firm believer in the spray part of antiseptic surgery, he had resorted to the atomizer in every case but one, and that one did as well without it as most do with it.

Dr. MONTGOMERY thinks Dr. Goodell should be congratulated upon his success, which is remarkable for operations in unselected cases in the United States. He thinks the knowledge of the safety attending the application of Monsel's solution to oozing abdominal surfaces very gratifying. He would have used it recently but for the fear of bad after-effects. He must, however, again enter his plea for the second ovary. In young women small ovarian cysts are common; they are frequently found in post-mortem examinations when there had not been the slightest evidence during life of their presence; and evidently these small cysts do not necessarily develop into large ones. The two cases of secondary ovariotomy reported by Dr. Goodell are not sufficient to warrant the rule of removing the second ovary when it is but slightly diseased. As a counterweight to Dr. Goodell's cases he would mention that, in the instance of a young married woman from whom he removed an ovarian tumor, and in which he left the other ovary, which was slightly affected, pregnancy has since occurred, followed by the delivery of a living child.

Dr. KELLY remarked that Dr. Keith had had remarkably good results from the application to oozing surfaces of a solution of

persulphate of iron. He has observed the gradual disuse of carbolic acid in washing-waters in operations. Dr. Kelly prefers boiled or distilled water, as used abroad, as he is sure that carbolic acid and other germicides are frequent causes of poisoning and bad results after operation. He asked Dr. Goodell what were his rules respecting the use of the drainage-tube.

Dr. BAER had experimented with Monsel's solution. In one case in which he used it he attributed the fatal result to it. The coagulation by the iron is unsightly, and he should now consider it a last resort. He had had very good results from pressure by packing sponges against the bleeding points, combined with external pressure. He withdraws the sponges at the last moment before tightening sutures, and then bandages the abdomen tightly.

Dr. GOODELL remarked that Dr. Montgomery was perfectly right in his defence of the second ovary, and he himself had performed double ovariotomy in only seventeen cases of the twenty-eight. He did not believe that every ovary studded with cysts would inevitably degenerate into an ovarian tumor. So in the case of slightly-diseased ovaries in young married women, he would be disposed either to let them alone or to remove the diseased parts only. But in women approaching the climacteric or where other conditions would make it advisable, he would remove the second ovary as useless in itself and as a possible source of future trouble. He has used the drainage-tube but three times during the past year,—once in the unfinished case of oöphorectomy, again in the case of torn bladder, and in the case requiring over thirty ligatures and with universal adhesions. In general, he uses it when a free oozing of blood is to be expected, but he regards it as a source of trouble and removes it as soon as possible.

W. H. H. GITHENS, M.D.,
Secretary.

PHILADELPHIA NEUROLOGICAL SOCIETY.

STATED MEETING, JANUARY 26, 1886.

DR. JOHN H. MUSSER presented some

NOTES IN THIRTEEN CASES OF TUBERCULAR MENINGITIS OCCURRING IN PRIVATE AND HOSPITAL PRACTICE.

Dr. WILLIAM OSLER then read a paper on

THE STRUCTURE OF CERTAIN GLIOMATA.

He desired to call attention to the histological character of certain brain-tumors which present peculiarities of structure separating them from the ordinary small-celled gliomata.

The specimens which he showed were from three cases, the features, clinical and anatomical, of which may be thus summarized:

Case I.—Girl aged 16, blind from third year; intelligent; head not large. Occasional convulsions and spasms of muscle of neck. Death sudden. Tumor occupied the surface of the left thalamus, and extended into the third ventricle. There was extensive dilatation of the lateral ventricles.

Case II.—Girl aged 15. Jacksonian epilepsy for over fourteen years. Small, firm tumor occupied the upper part of ascending convolution.

Case III.—Man aged 40. Head-pain, mental disturbance, drowsiness, the chief symptoms. Tumor the size of a lemon occupied left anterior lobe of brain.

The physical characters of these three tumors differed considerably. In Case I. the mass on the thalamus was firm, but the portion projecting into the third ventricle was soft, grayish in color, and looked like an actively-growing neoplasm. In Case II. the small tumor at the upper part of the ascending frontal convolution resembled a patch of sclerosis, while in Case III. the tumor had a large central area of fibro-caseous change, with a peripheral zone of actively-growing grayish-red tissue.

Histologically, these tumors are similar in the dense felt-work of fibres which make up the chief mass of each, the fibres varying somewhat in thickness and in closeness of arrangement. Careful observation of teased specimens shows that the fibres are, for the most part, in connection with cells, and so far the growths conform to the type of glioma. True, we do not find here the typical arrangement of small cells with delicate protoplasm and numerous fine ramifying processes which gives to many gliomata an appearance not unlike that of a small-celled sarcoma. There are gliomata, however, with larger and more irregular cells and with coarser fibres than the description in text-books would lead us to suppose, and it was more particularly to certain characters in the cells of these tumors that he wished to call attention. A study of teased fresh specimens can alone give a clear idea of the shape, size, and relations of the cell-elements.

The following varieties of cells occur in these growths:

1. The ordinary "spinnen" or spider-cell, with many processes, which may be regarded as the characteristic cell of the glioma. These present a considerable variation in size: many are not larger than colorless blood-corpuscles, others double or treble the size. The smaller have more delicate processes, which in sections of hardened specimens may not be apparent. Some of the larger of the cells look not unlike multipolar nerve-cells.

2. Large, unbranched, spindle-shaped cells, with greatly elongated processes. These re-

semble enormous connective-tissue corpuscles, and the processes may be traced until they taper to extremely fine fibrils; others are scarcely spindle-shaped, but present flat, ribbon-like processes. Some of these cells are among the largest and most remarkable met with in tumors. In Case I. the mass in the third ventricle was composed largely of them, and isolated ones measured as much as 0.4130 of a millimetre. They present usually single large nuclei, and the protoplasm of the cell is either homogeneous or finely granular. In Case III. these forms were also very abundant, but in Case II. they were not numerous.

3. Cells which resemble closely in appearance large ganglion-cells of the nerve-centres. They present a dark granular protoplasm, large nuclei, and one, two, or more processes, which either run singly or finally branch. The most remarkable looking are those with a single process springing from a balloon-shaped cell. Others have a process from each end of the cell-body. They are usually much larger than the spider-cells.

4. In Cases I. and III. there were structures of very curious aspect, which probably may be regarded as derivatives of the large fusiform-shaped corpuscles. These were remarkably translucent, band-like fibres, tapering slightly at each end, but without nucleus or granular protoplasm. From their close resemblance in form to the spindle-shaped cells, and from the fact that these latter often present a remarkable translucency, I think we may regard these peculiar fibres as resulting from a vitreous or hyaline transformation of the large spindle-cells.

These tumors conform to the variety described as neuro-glioma by Klebs, who holds that the large ganglion-like cells found as such important constituents of these growths are derived directly from the nerve-cells of the gray matter, and that in the development of this variety all the elements of the nerve-tissue participate. Certainly the resemblance between many of the large cells and nerve-elements is very striking, but I have not been able to satisfy myself of their relation to the pre-existing tissue parts. This is, of course, extremely difficult; but in a careful study of sections taken from the advancing regions of the growths I have not met with appearances which would lead me to suppose that the nerve-cells were in process of proliferation. Klebs states that he has demonstrated by means of osmic acid and gold chloride the nature of the cells and their processes; but this has not been confirmed, and I could not determine that the cells or fibres described above behaved in a characteristic manner with these reagents. That they are probably connective-tissue elements seems probable from an examination of a large number of the cells in teased preparations. Gradations and intermediate forms can be seen between cells closely resembling unipolar or bipolar nerve-ganglia and the typical spider-cells with innumerable processes. Gliomata of this form are not uncommon. Klebs described fourteen or fifteen, and, of five cerebral tumors of the glioma-type which I have met with, only two were of the small-celled variety.

Dr. WHARTON SINKLER reported

A CASE OF BRAIN-TUMOR.

Miss S., æt. 52. Mother, maternal grandfather, great-grandfather, two maternal uncles, and two brothers died of phthisis. Paternal ancestors long-lived. No cancer. Healthy and well up to four years old. Then had a serious illness, spoken of by some as "brain fever;" another person says dysentery. Seemed to recover entirely from this, and was bright, well, and agreeable. Was not very intelligent mentally, but not by any means deficient. Catamenia first appeared at eighteen years. At seventeen years friends noticed a change in her: she was irritable, cross, and peculiar about many things. This condition of things continued through the remainder of her life, all the peculiarities becoming intensified. She was a great reader and a great eater. She was fond of literary pursuits, and spent a considerable amount of time in writing and painstaking composition. She never had convulsions, as far as known. At twenty-five years she was examined as to her mental condition by Dr. William Kirkbride, and he decided that, although not mentally vigorous, she was not insane.

For five or six years before her death, say forty-five years of age, she seemed to grow stouter, less inclined to work, and in walking seemed to move slowly and with difficulty. For three or four years before her death there was a drooping of the left corner of her mouth, most noticeable in smiling or speaking. This gradually increased. For eight or ten years she had had headaches.

In the summer of 1885 she was at Atlantic City, and had two or three attacks of violent headache associated with unconsciousness. These lasted several days at a time. She came under my charge in September, 1885. She then showed slight left facial paralysis, but no loss of power in arm or leg of either side. She complained sometimes of pain in the head, sometimes in the shoulder or neck; seldom seemed to have persistent pain in one place. She had an attack of unconsciousness with severe headache; screamed with pain, but could check herself, and when asked what was the matter said she had pain, but could not state exactly where it was. At times she talked incoherently and spoke of having seen persons whom I knew she had never seen. She was unwilling to leave her bed, but, if she could be persuaded to get up, could walk about. Her appetite was good, but there were indigestion and constipation. No vomiting. Vision seemed good, but the

eye-ground was not examined. She was eccentric in her way of talking, and said many things with the evident intention of creating surprise.

At my suggestion, she was taken to a country town in the vicinity of Philadelphia, and was there under the care of Dr. J. Reeve. After reaching this place, she complained of pain in the right side of the head and seemed unable to walk; would fall into a semi-unconscious condition, which would last for some hours. The temperature became elevated, the facial paralysis became more marked; but, although no paralysis of the limbs, there was general muscular weakness. The patient died on October 26, 1885.

The post-mortem examination was made by Dr. H. Wharton. Upon exposing the membranes of the brain they were found markedly congested, and the dura mater was very adherent to the petrous portion of the temporal bone on the right side. Brain removed, membranes divided and turned aside. Upon left side there was no apparent lesion. On the right side some bulging of the membranes was apparent in the region of the fissure of Sylvius, and, upon dissecting them off, they were found very adherent to a tumor, larger than an English walnut, growing from the fissure of Sylvius about the line of the fissure of Rolando. The tumor was dead-red in color, stood out from the brain-tissue, and was dense to the touch. There was some effusion into the ventricles.

Dr. De Schweinitz made a microscopic examination of the growth, and sent me the following report: "The small portion sent for examination was hardened first in a solution composed of Müller's fluid one part, and methylic spirit three parts, for six weeks, and then in alcohol. Sections were cut, stained with carmine, and mounted in balsam. In the periphery the growth shows a structure composed of more or less perfectly developed fibrous tissue; more interiorly the stroma of the tumor is made up of numerous, variously-sized, dilated blood-vessels, sometimes empty, but for the most part filled with corpuscles. Between these are numerous small round and large spindle-cells (sarcoma-tissue) scattered through the growth, sometimes singly, often in groups; there are round, yellowish-white bodies, which are probably amyloid in their nature. The tumor may be properly classed as an *angio-sarcoma*."

The growth, as may be seen, is spherical in shape, and springs up out of the fissure of Sylvius. The points of interest in the case to me are these. First, the probable long standing of the growth. It is likely that it began at the age of eighteen years, when mental peculiarities first showed themselves. Secondly, the absence of most of the symptoms peculiar to brain-tumor. There were no convulsions, no vomiting, no defects of vision, and no pain localized in one particular spot. The facial paralysis was not noticed until three or four years before death. There were many marked hysterical symptoms which masked the true nature of the disease. These, I think, are often met with in brain-tumors in women.

(To be continued.)

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, JANUARY 25, 1886.

The President, DANIEL LEWIS, M.D., in the chair.

ON THE ADVANCED OPERATIVE TREATMENT FOR THE RADICAL CURE OF HERNIA.

DR. ROBERT ABBE, the author of the paper, showed the desirability of effecting a radical cure of troublesome herniæ, if possible, and briefly referred to operations which had from time to time been brought forward with the hope of effecting this result. Speaking of those which had been advanced prior to the recent open method and Hilton's injection-method, he said their safety had recommended them, but their failure to effect a radical cure condemned them. It would also seem that this remark might almost be applied to Hilton's method. In view of the difference in the statistics given by different authors who had practised the open method, it was desirable to place before the profession the exact histories of cases so operated upon.

Dr. Abbe then gave the history somewhat in detail of twenty-one cases in which he had practised the open method, that employed by Banks, of Liverpool, and others. There were minor points of difference in the operation as it was practised by surgeons at different places. In Liverpool, for example, it is the custom to employ silver wire in closing the inguinal ring, while others employ catgut for this purpose.

In sixteen of the cases there was not strangulation, and in a portion of the others the symptoms of strangulation were not very marked. The results of the treatment led the author to ask two questions: first, was the open operation a safe one? and, second, did it effect a radical cure? If we should judge by the statistics of Liverpool surgeons, we must admit that it was safe; but such good results had not been obtained outside of that city. Other statistics showed a death-rate of one case in eight. It was true, however, that this showed the result of treatment in the worst cases, for only such had usually undergone operation. There were dangers arising from adherent intestine, old adherent bands, incarcerated omentum, fatty heart, feeble health, etc. Again, in this operation we had to face the fact of possible hemorrhage. Banks, of Liverpool, had referred to a case of hemorrhage, which, however, recovered

after laparotomy and securing of the bleeding point. The accident had also occurred in the hands of experienced surgeons in this city. It occurred in one of the cases reported by Dr. Abbe in the manner in which he believed it usually occurred,—namely, by shrinkage of the omental tissue, which was really but a mass of fat, and loosening of the ligature. To avoid this accident he advised the use of carbolized silk, ligaturing the broad and thick mass of omental tissue three, four, or even five times, and, in addition, securing any bleeding vessels on the cut surface. Peritonitis, suppuration, and hemorrhage had been the three bugbears which had led surgeons to let the hernial sac alone. But the greatest danger from peritonitis was due to the development of erysipelas, and the occurrence of this accident was not very likely if antiseptic methods were strictly observed. Inasmuch as hemorrhage had occurred in the hands of the most careful and experienced surgeons, it might be a question whether this accident could be with certainty guarded against in all cases. The possibility of its existence was thought of in the case referred to, and laparotomy had been taken into consideration; but, inasmuch as special care was taken during the operation to guard against subsequent hemorrhage, and as the red appearance of the man's face (due to drink) seemed to weigh against its presence, this was not performed. In one of the twenty-one cases death occurred from fatty heart and intestinal obstruction brought on by the relations of the returned omental stump. It was not probable, even had laparotomy been performed, that the constricting band could have been relieved. In a third case, Dr. Abbe performed the open operation for the radical cure of hernia, and at the same sitting operated upon some varicose veins of the leg, which resulted in suppuration and death, although the hernial wound was doing well.

The author was strongly of the opinion that suppuration and union by granulation in the canal and about the ring led to a much better final result than did primary union. This was also the estimation of the granular process by English surgeons. Adhesive inflammation about the ring, excited by whatever method one might use, was delusive. The induration following Heaton's method was usually absorbed within a month. If we could bar the ring tightly and keep it barred, we might keep back pressure, but the catgut suture became absorbed within a week, and allowed the strain to come upon the soft parts too soon. The patient should support the soft parts from without many weeks, and perhaps many months, after the operation. With regard to a return of the hernia, Dr. Abbe thought it extremely probable that there would be a recurrence within a year or two. It was much less likely to follow an operation upon a femoral hernia than upon an inguinal hernia. But recurrence of the hernia was not a sign of failure of the operation, for the patient was almost always restored from complete invalidism to perfect health and ability to do his work. The sixteen unstrangulated herniæ which he had operated upon had all been unmanageable, and all of the patients expressed great satisfaction at the result of the operation.

Dr. A. G. GERSTER had performed the radical operation in twenty-five or more cases. In eight or nine there was no strangulation, but the distressing symptoms were so acute that the patients were unable to wear a truss or to attend to their affairs. The chief features of the operation as he performed it were dissection of the sac, sewing up of the neck of the sac by catgut suture in a manner resembling a purse-string, replacement of the stump of the sac, then sewing up the pillars of the external abdominal ring by several superimposed rows of sutures of catgut.

He thought the results were better in cases in which the ring had not become largely distended. Of the twenty-seven or more cases, he lost three, in each of which the condition had been such as to call for herniotomy. One patient died of necrosis of the gut, which was returned under the false impression that it was viable. Another died of follicular diphtheritic inflammation, and the third probably of septic peritonitis from necrosis of the gut, but an autopsy was not obtained to confirm the diagnosis. In all the cases in which herniotomy had not been indicated, the patients recovered without any disturbance. He therefore thought the operation was safe in the hands of one who was familiar with antiseptic methods; but he did not believe a radical cure was effected. There would be a relapse; but patients were enabled to wear a truss with comfort and to go about their usual work, whereas before they were hopeless invalids.

Dr. R. F. WEIR said that in herniæ not strangulated he had performed the operation eight times, and he thought himself justified in undertaking it in cases in which the hernia was large, perhaps irreducible, rendering a truss useless and disabling the patient for work. But Dr. Weir had seen three deaths after the open operation from hemorrhage, occurring in the practice of surgeons of experience. In two or three of his own cases the amount of suppuration and constitutional disturbance after the operation had been very considerable, and he was anxious lest peritonitis should develop. If, after the best of these operations, attended by even a moderate amount of risk, the patient was obliged to wear a light truss, he would ask, why extend the operation to those cases of reducible herniæ which could already be kept up by a light truss? Dr. Weir had not yet lost faith, in cases of mild herniæ, in Dr. Heaton's injection-method. He thought it would cure from one-third to one-half of

such cases, and he should be unwilling to adopt the open operation.

Dr. O. A. WHITE presented a modification of Wutzer's instrument for invaginating the inguinal canal and exciting adhesive inflammation of its walls in cases of hernia. His modification was made by Tiemann years ago, at a time when the slave-holders were anxious to own a sound negro instead of one who had rupture. The modified instrument had two needles, while the original had but one and was heavier than its substitute. Dr. White had used the instrument in at least forty cases, and not more than five had to be operated upon twice.

Dr. ABBE closed the discussion.

THE DIAGNOSIS OF SMALLPOX.

Dr. P. ALBERT MORROW then read a paper on this subject, the importance of which, he said, was evident from the fact that atypical and modified forms of smallpox presented many features closely resembling various eruptive diseases, and from the fact that in this city physicians were required by the Board of Health to report regarding the nature of the disease within twenty-four hours, and if a false diagnosis were made he would expose himself to a suit at law. During the period from 1880 to 1885 two thousand five hundred cases of smallpox had been admitted into the hospital. Thirty-five cases were wrongly diagnosticated as smallpox, and in eleven cases variola was diagnosticated otherwise. A much larger number of cases were sent to the reception hospital as cases of smallpox, but were not transferred, the diagnosis of smallpox having been erroneously made. During a recent period the number of cases of smallpox had been comparatively small, while the number of cases reported as smallpox was large. In at least two of these cases the mistake was made by physicians of large experience, and showed that a correct diagnosis within twenty-four hours, as required by the rules of the Board of Health, was at times impossible. The diseases for which variola had been mistaken, or which had been mistaken for variola, were varicella, varioloid, measles, scarlet fever, typhus fever, typhoid fever, syphilis, urticaria, sudamina, herpes, acne, etc. The mistake was most frequently made with regard to measles. Dr. Morrow then proceeded to point out the differential points between atypical or modified forms of variola and these diseases.

In his concluding remarks the author referred briefly to the evidence of characteristic marks of vaccination as influencing diagnosis. Clinical experience proved very conclusively, he said, that vaccination, no matter how efficiently or recently performed, did not always prevent smallpox. In some cases it did not materially mitigate the severity of the eruption. On the other hand, it was well to remember that, exceptionally, a mild modified form of smallpox might occur in persons who had never been vaccinated. The absence of all marks of vaccination, no matter how mild the symptoms, did not necessarily exclude variola. An attack of smallpox did not necessarily diminish susceptibility to vaccination.

The paper was discussed by Drs. McLaury, Sell, Weinberg, Judson, Mittendorf, Abbe, and the author.

Dr. MORROW was elected delegate to the State Medical Society, to fill the vacancy left by the resignation of Dr. Alexander.

Dr. GOUVERNEUR M. SMITH read a report from the Committee on Contagious Eye-Disease, which was accepted and its recommendations adopted.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held February 4, 1886, the President, A. JACOBI, M.D., in the chair.

THE INTRA-CEREBRAL TRACTS: THEIR PHYSIOLOGY, AND ITS BEARING UPON THE DIAGNOSIS OF LESIONS OF THE CENTRUM SEMI-OVALE.

Dr. M. ALLEN STARR, in his paper, said that such authorities as Nothnagel, Charcot, and Strümpell admit that few rules for guidance could be given, and that at present there are no definite symptoms assigned to diseases of the centrum semi-ovale. But the subject of lesions of this part of the brain has an immediate practical bearing, for in the journals during the past year there were recorded several cases of operations for the evacuation of cerebral abscesses and the excision of tumors. But the surgeon is dependent upon the neurologist to tell him where to operate, and we know that tumors and abscesses, the legitimate field for operation, lie chiefly in the centrum semi-ovale. The inductive method has not been so satisfactory here in making a diagnosis as in lesions of the cortical substance. Lesions of the centrum ovale are not very common, and consequently are not often suspected during life. There are also many symptoms in each case which must be searched for by the examiner, as they are of a nature to elude the notice of the patient, such as disturbance of the temperature-sense, of vaso-motor activity, of exact limitation of the visual field, etc. Dr. Starr showed the importance of a knowledge of the anatomy of the intra-cerebral tracts, and described the three sets of nerve-fibres composing it,—namely, the projection, the commissural, and the association systems,—and also gave the prevalent views of their physiology.

With regard to the association fibres, Dr. Starr said he would suggest, without going very deeply into the subject of psychology, that they form the physical basis for the association of concrete memories. They are necessary to the union of different memories

in a whole, to the formation of a concrete idea. He did not allude to processes of reasoning. Having, then, a knowledge of the anatomy and physiology of the association fibres of the centrum ovale, we also have a set of symptoms referable to their destruction. But intelligent questioning of the patient is necessary in order to learn what those symptoms were. For instance, in the case of the fibres associating the auditory with the motor speech-areas, the symptoms to be elicited seem to be very simple. Could the patient talk correctly? Could he repeat at once a word spoken to him? These were questions which any one would ask who examined a case of aphasia. But this was not sufficient. Could the patient read understandingly to himself and tell what he had read? This would test the occipito-temporal tract. Could he read aloud? This would test the occipito-temporo-frontal tract. Could he write what he saw? This would test his occipito-central tract. Could he write what he heard? This would test the temporo-central tract. Could he write what he spoke to himself in a whisper? This would test his fronto-central tract, etc.

Dr. Starr thought it would be evident that a lesion of the centrum ovale might give rise to three sets of symptoms, referable to projection, commissural, and association fibres. The important fact would at once be evident that these symptoms must be associated in any given case, and it was upon the fact of such association of symptoms that the diagnosis of lesions of the centrum ovale must depend. Monoplegia alone might be caused by disease of the cortex or of the centrum ovale, hemiplegia by capsular or centrum ovale disease. But if in either case it was the centrum ovale which was affected, there would be in addition to the paralysis a suspension of action of commissural and association fibres. The commissural fibres being destroyed, simultaneous bilateral symmetrical motions would be suspended. The association fibres being destroyed, certain mental associations would be affected. For example, a lesion in the centrum ovale of the occipito-temporal region would produce hemianopsia, because it would involve the visual tract of the projection system. It might also produce a peculiar mental condition known as word-blindness, in which the patient was no longer able to associate a word or letter seen with its corresponding sound, or with the motion necessary to write it. Charcot has reported such a case which Dr. Starr, who had seen the patient with him, gave in detail.

Dr. Starr said that in all cases of obscure brain-disease we should examine all the functions of which we have any knowledge, trusting to the future to explain peculiar symptoms. It seemed to him that the way to solve the problem was to reason from anatomy and physiology to the probable results of lesions in the centrum ovale, and then in every case to examine for the symptoms which theoretically might occur. In this way no latent symptoms would be overlooked, and after a time we might have many new symptoms now unsuspected, which, in connection with lesions found at post-mortem examination, would warrant the formulation of certain diagnostic signs of disease of the centrum ovale.

PERMANENT DRAINAGE IN ASCITES.

Dr. AUG. G. CAILLÉ related the histories of two cases.

About four years ago he saw an elderly gentleman suffering from cirrhosis of the liver, in whom the symptoms depending upon ascites were so marked as urgently to demand tapping and repetition of the operation. He was tapped nine times in the course of seven months, a pailful of serum being removed each time. Before the tenth operation Dr. Caillé determined to attempt permanent drainage, although the danger of exciting a peritonitis or other serious complication was fully appreciated. An incision an inch in length was made in the median line half-way between the umbilicus and symphysis pubis, a trocar and canula introduced, the trocar withdrawn, and a rubber tube inserted. After withdrawal of the fluid the tube was allowed to remain, iodoform being put upon the dressing at the mouth of the tube, and the fluid allowed to drain and be absorbed by towels. Some eczema developed under the dressing, which disappeared under suitable management. After drainage had been established the œdema disappeared rapidly, the heart-action improved, the breathing was freer, the troublesome cough disappeared, the bowels became regular, the appetite improved, and the patient became able to go about, wearing all the while the tube. The rubber canula remained *in situ* about nine weeks, when it was removed, and at the end of another four weeks the opening closed. The patient was able to be about his duties for nine months, there being no return of the œdema or of the ascites. After nine months his strength began to fail, and he finally died of heart-failure. Two weeks before death there was a return of slight œdema of the ankles. At the autopsy cirrhosis of the liver and fatty heart were found. Careful inspection of the peritoneum at the seat of puncture revealed no evidence of inflammation.

The second case was similar, and in addition there was marked purpura hæmorrhagica, epistaxis, bleeding gums. The patient had no appetite, and was unable to sleep. He was treated as was the other patient,—in this case a rubber tube being employed to conduct the drainage from the rubber canula to a bucket by the bed containing a carbolic solution. The tube was worn for seven weeks. The ascites and œdema disappeared. The appetite improved. There was, in short,

improvement in all the symptoms. The patient was able to pass ten weeks with his family in the Catskills, and continued to live a comfortable existence until the spring of 1885, when he died suddenly, as was supposed of heart-failure, when attempting to get out of bed. There was no return of the ascites. An autopsy was not allowed.

In his general remarks Dr. Caillé considered four questions:

1. What are the symptoms and dangerous mechanical effects of ascites?

2. How is the collateral circulation established in cirrhosis of the liver?

3. Will the absence of intra-abdominal pressure or pressure from ascites promote collateral circulation and functional activity of important organs, and thereby prolong life and add to the comfort of the patient?

4. How is drainage best accomplished?

After considering these questions, the author said he was inclined to believe from this limited experience that we need not fear peritonitis so much when ascites is present as under other circumstances. Too much importance, however, should not be attached to these two cases, for the number was too small to judge from them of the value of this procedure. It was the author's opinion, however, that it should be given a trial in cases of ascites which required two or more tappings for reaccumulation of fluid.

The PRESIDENT said it appeared to him that what Dr. Caillé had done in these two cases was what might have occurred spontaneously. Probably some of the gentlemen present had seen cases of extreme ascites in which spontaneous rupture of the abdominal walls had taken place. He had seen some such cases. The place of rupture was usually in the median line, particularly at the umbilicus. In such cases there was, of course, a permanent fistula established, and, instead of allowing it to occur at a spot which was not convenient or pleasant, he thought it was better for the surgeon to make the opening where he wished it should be established. There was such a case in the German Hospital the past year,—that of a heavy German, in whom spontaneous rupture took place at the umbilicus, allowing of the escape of the ascitic fluid. It healed and reopened several times in the course of a few months. The patient felt so well satisfied with his condition that he left the hospital, but naturally the shrinking liver and swelling spleen still remained.

The President then described a case of encysted ascitic fluid which occurred in his ward in the Bellevue Hospital last year, in which the physical signs were almost exactly those seen in a patient over twenty years ago. In the case seen long ago he made the diagnosis of ovarian tumor, and, although post-mortem examination proved his error, he still thought that the diagnosis of ovarian cyst was the only one justified by the signs during life. He had this case in mind when contemplating an operation upon the patient in Bellevue Hospital, yet the signs were so plainly those of an ovarian cyst that an incision was made, when it was found that the fluid was ascitic, limited by adhesions. Permanent drainage was then established for a time, and the patient improved and left the hospital. He had since heard that the fluid had reaccumulated. There was a family history of tuberculosis, and it was probable she had tubercular peritonitis.

Since learning of Dr. Caillé's operation, Dr. Jacobi had performed it upon a man suffering from cirrhosis of the liver, with jaundice, purpura, epistaxis, loss of strength, ascites, dyspnœa, etc. As his strength was constantly diminishing, and the symptoms demanded relief, he established permanent drainage midway between the umbilicus and urinary bladder in the manner described by Dr. Caillé, leaving the tube in several weeks,—until the patient's death, for he had been dying for some time. The canula was obstructed by wax during the night, drainage being continued only during the day. The patient felt relieved. Post-mortem examination revealed no peritonitis. Dr. Jacobi thought the operation of Dr. Caillé a good one, and he would repeat it whenever a suitable case came under his observation.

The question of medicinal treatment of cirrhosis of the liver having been raised, the President said that small doses of corrosive sublimate, long continued, were beneficial in all forms of interstitial inflammation, whether in the form of a myelitis, a nephritis, or a hepatitis. Of course when the disease was advanced its progress could not be stopped, but when only a portion of an organ was involved this treatment might enable us to prolong the patient's life indefinitely.

Dr. LINDLEY said that in South Africa the Dutch settlers used honey as a popular remedy in cirrhosis of the liver. In one case in which he had resorted to tapping for accumulation of fluid in the peritoneal cavity, a woman advised the use of this article. The man took a pint of liquid honey daily, and recovered.

Dr. SHERMAN suggested that there might have been medicinal properties from the flowers in the honey.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held January 27, 1886, the President, JOHN A. WYETH, M.D., in the chair.

INTESTINAL VOLVULUS.

Dr. R. VAN SANTVOORD presented specimens from a case of volvulus of the sigmoid flexure. The patient, a male, aged 45 years, had for thirteen years been an inmate of the

Randall's Island Pavilion for the Insane. Being demented, he was unable to give an account of his condition. On June 30, 1885, the house-physician noticed that he walked in a bent position and went frequently to the water-closet. The abdomen became largely distended, and on the fourth and fifth days cathartics were given, but without effect. There was no vomiting. Dr. Van Santvoord saw the patient for the first time a day or two afterwards. Twenty feet of tubing were introduced into the gut, and an injection made of warm water; but on withdrawing the tube none of the water escaped. Before reaching a diagnosis, a hypodermic needle was introduced through the abdominal wall, and a large amount of gas escaped. This fact seemed to point to distention of the colon rather than of the small intestine. Tenesmus indicated volvulus of the sigmoid flexure. Ability to pass the tube beyond the obstruction pointed to a slight twist of the gut, which recurred on withdrawing the tube, preventing escape of the fluid injected. The subacute character of the symptoms indicated obstruction rather than strangulation.

Nine days after attention had been called to the patient's condition, laparotomy was performed under antiseptic precautions. The incision extended from just below the umbilicus, in the median line, a distance of four inches. After the abdomen had been opened, the gut being greatly distended with gas, the aspirator-needle was introduced in an oblique direction, allowing much of the gas to escape. Then, on introducing the hand, the sigmoid flexure was found to have made half a twist on its axis. Reduction was easy. It was thought best not to suture the opening made by the hypodermic needle, and through which some gas had escaped after its withdrawal. A copious flow of fluid fæces took place through the rectum before the abdominal wound was closed. For three days the patient did fairly well, having several loose passages each day, and the abdomen became sunken. On the fourth day the temperature went up, the patient began to lose strength, and the abdomen became distended, but no other abdominal symptoms were manifest. Death from exhaustion took place on the sixth day after the operation. The autopsy revealed pneumonia. The peritoneum was firmly closed at the site of the incision, and there was no sign of inflammation about the wound except a few drops of pus in the line of a continued suture. The colon was much distended. There had been no recurrence of the twist in the gut, which had occurred at two points of narrowing in the sigmoid flexure, the distended portion of gut lying between the narrowed points having been thrown over forward from right to left, making half a twist. The peritoneum at a point where the colon was greatly distended had ruptured. There were no signs of acute peritonitis. At the point where the puncture had been made there was some brown pigment, but the opening had closed completely.

ELONGATION OF THE SIGMOID FLEXURE THE CAUSE OF MARKED TYMPANITES.

Dr. L. Emmet Holt presented specimens which were interesting in connection with the case related by Dr. Van Santvoord. They consisted of the intestines removed from the body of a child which had been under his observation for three months. The child died recently, after an illness of three days, from an acute disease. The point of interest in the case was the fact that the child had had attacks of tympanites which lasted sometimes a week, and so marked that respiration was interfered with. At times the tympanites would disappear almost entirely, and at other times it was much relieved by the introduction of a tube into the rectum, when much gas would escape. The bowels were free, and there were no symptoms pointing to intestinal obstruction. There was a family history of tuberculosis, and for this reason it was thought possible there might be tubercular peritonitis. It appeared from the autopsy that the cause of the troublesome tympanites had been a great elongation of the sigmoid portion of the colon, which was reflected upward so as almost completely to cover the abdominal viscera. This abnormality was thought to be congenital. There was no real obstruction, and no distention with fæces. The mesenteric attachment of the gut was very long. There was no peritonitis.

The President thought surgical interference should be resorted to early in all cases of intestinal obstruction. We should not wait twenty-four hours even for the clearing up of the diagnosis when there were strong suspicions of intestinal obstruction. The exploratory operation would not be in itself a dangerous procedure, and in the large majority of cases it would enable us to discover the cause of the obstruction and to remove it. With regard to puncture for the relief of intestinal distention with gas, he had resorted to it in several hopeless cases for the purpose of relieving pain, and he had always found at autopsy that the holes remained patent, so that gas could escape through them. He recalled one case in this city in which multiple punctures were resorted to during an operation to allow the escape of gas from the overdistended gut, and the patient recovered.

Dr. Carpenter related an anecdote in which it appeared that the late Dr. Parker during a lecture cautioned the students not to resort to puncture to allow of the escape of gas from an overdistended gut. The late Dr. Stephens, entering the hall a few minutes later, was asked if he had any remarks to make. He said, pointing to a diagram hanging upon the wall, that a very embarrassing situation for an operator to be placed in was

to have a large coil of intestine protruding from the abdominal wound during an operation for strangulated hernia. There was no more satisfactory way to relieve this, he said, than to take a fine cambric needle and gently puncture the intestine, and no harm would come from it. Thus two eminent surgeons entertained entirely opposite views regarding the management of the same condition. Dr. Carpenter added that there are a sufficient number of unfavorable cases on record to put one upon his guard against indiscriminately resorting to puncture of the intestine.

Dr. J. LEWIS SMITH had seen satisfactory results from injections of large quantities of warm water into the bowel, the pelvis being raised and the abdomen kneaded during the injection. In one case he succeeded in reducing the obstruction after it had existed three days. He had no doubt, however, that many lives might be saved by an early operation, as Dr. Wyeth had recommended.

Dr. VAN SANTVOORD remarked that, according to the statistics, the mortality from intestinal obstruction is great; but they are probably more or less misleading, as they represent severe or prolonged cases. He thought it probable that a number of cases of obstruction or volvulus occurred which recovered before the symptoms became very marked, and which consequently were not reported. He thought he had seen several cases of that kind. The surgeon principally sees severe cases, such as enter the hospitals, and he is likely to base his opinion as to the importance of an operation upon such cases.

The PRESIDENT was still of the opinion that if, in all cases in which the symptoms were fairly indicative of intestinal obstruction, an early operation were performed, the percentage of mortality would be reduced.

REVIEWS AND BOOK NOTICES.

A PRACTICAL TREATISE ON MASSAGE: its History, Mode of Application and Effects, Indications and Contra-Indications. With Results in over Fourteen Hundred Cases. By DOUGLAS GRAHAM, M.D. New York, William Wood & Co. Cloth, 8vo, pp. 286.

The popularity of the treatment advocated by Weir Mitchell, in which passive exercise and massage occupy such a prominent position, has led to a general desire for more information as to the requirements of massage in order to secure its intelligent and scientific application. Dr. Graham, who has for years identified himself with this subject by his contributions to the medical press, has therefore rendered a real service to the cause of scientific medicine by publishing the only systematic work upon this subject in the English language, so far as we are aware. In sixteen chapters he considers the history, technique, and therapeutic applications of massage to diseases of special organs, as well as to disorders of the nervous and muscular systems. The influence of massage upon assimilation is best demonstrated in the treatment of neurasthenia, locomotor ataxia, chorea, writer's cramp, and other neuroses connected with or dependent upon impaired nutrition.

We have deferred noticing this book, indeed unduly, until time was afforded for a thorough examination, and we can say, after perusal, that it abounds in information upon a subject which modern medicine has treated with strange neglect. No one can rise from reading this work of Dr. Graham's without having increased confidence in restorative medicine or feeling that he has enlarged his own powers in the treatment of disease.

THE PRINCIPLES AND PRACTICE OF MEDICINE. By the late CHARLES HILTON FAGGE, M.D., F.R.C.P. Vol. II. P. Blakiston, Son & Co., Philadelphia, 1886. Royal 8vo, pp. 883.

The second volume of this great work contains sections on Diseases of the Heart and Blood-Vessels, Diseases of the Alimentary Tract, Diseases of the Liver, Affections of the Urinary Organs, General Diseases affecting the Joints, Diseases of the Bones, and Diseases of the Blood. It concludes with an excellent systematic consideration of diseases of the skin, by P. H. Pye-Smith, M.D. Full subject and author indexes are given, and to the work is appended a brief Memoir of the Author, whose early death was a deep loss to medicine.

The amount of erudition, clinical observation, and pathological investigation which are shown by the pages of this work is surprising, and indicates a mind of rare gifts, accompanied by untiring industry and zeal for the acquisition of facts. In Bacon's classification this work would come under the caption of books which are to be taken in and digested. A brief notice only fails to do it justice. As it is, it forms an enduring monument to the memory of a talented, industrious physician, who served his generation well.

NEW REMEDIES AND CLINICAL NOTES.

SOME USES OF FRIEDRICHSHALL WATER. —Lauder Brunton, Professor of Therapeutics at St. Bartholomew's Hospital, London (*The Practitioner*), says, "The therapeutical range of Friedrichshall is highly esteemed by the leading German physicians: Mosler and Thierfelder find it of great service in habitual constipation and various digestive liver-affec-

tions; Scanzoni in the constipation of pregnant women; Schröder and Veit in uterine congestions and inflammation, and especially in chronic metritis; Weber in catarrh of the bladder; and Sir Henry Thompson in the prevention of calculous disease and the prophylactic treatment of gravel. Löschner, Helft, and Mosler speak highly of its use, combined with suitable exercise and diet, in the torpid forms of struma, and in scrofulous children. The opinion of these authorities is likely to reinstate Friedrichshall as a favorite laxative."

Antiseptic Gauze for Surgical Dressings.—Dr. R. F. Weir, at the last meeting of the Surgical Society of New York, recommended the following as a decided improvement over Billroth's composition for applying to gauze: resin, ten parts; castor oil, six parts; alcohol, fifteen parts; iodoform, five parts.

The Ubiquitous Bacillus.—Dr. G. Puerta (*El Siglo Médico*) claims to have detected a comma-shaped bacillus in laudanum: so that clinicians who depend upon their microscopes for their ability to detect cholera will be under the necessity hereafter of examining their medicine, if it contains laudanum. And if the medicine, why not examine with equal care all the food and drink?

MISCELLANY.

Oleomargarine.—The subject of the adulteration of food-products is one of growing importance, which is now coming prominently before the various State Legislatures. The manufacture of oleomargarine is one of the greatest of these grievances, and the report of the Dairy Commissioner of the State of New York, just presented to the Legislature, is therefore an interesting document. The highest court of New York, it will be remembered, recently decided that the absolute prohibition of the manufacture of oleomargarine was unconstitutional; yet vigorous efforts have been made all through New York to prevent the compound being sold for genuine butter. This result, the Dairy Commissioner says, has been largely accomplished. Nevertheless, one of the leading papers of the State has this account to give of the present condition of the traffic: "Oleomargarine is a greater enemy to the farmers, and through them is doing more injury to our prosperity, than is generally imagined. The figures of the growth and sale of this bogus butter are truly alarming. In 1880 the country exported 39,236,655 pounds of butter and 20,000,000 pounds of oleomargarine; but in 1885 the exports of oleomargarine nearly reached 38,000,000, while the exportation of butter declined to 21,638,128. Fifty million pounds is the present magnitude of the manufacture of the bogus article, out of which dishonest men are evidently making enormous fortunes. The law prohibits the fraudulent sale of the imitation product; but it nevertheless goes on, despite the exertions of the authorities to prevent it: the claim, indeed, is made that the law is so full of loopholes that it is almost impossible to secure a conviction under it. The perpetuation of the valuable dairy interests of this State can only be secured by the most complete protection in this particular that can be given them, and the present Legislature can undertake no more important service than is involved in filling the gaps in oleomargarine legislation."

A Question of Expert Testimony.—One of the Illinois courts has recently had before it the question whether a physician could refuse to answer inquiries about matters where he was interested until his fee had been paid. The physician, it seems, had been called to attend a person who had been injured in a fight (struck with a policeman's billy), and, the affray afterwards coming before the courts, the physician was called to testify in regard to the condition in which he found the man. He testified without any objection on his part as to the patient's physical condition, and was then shown a policeman's "billy" and asked if a blow struck with it on the head would not be likely to produce upon a person a condition similar to that in which he found the patient. The physician then asked the court whether the question did not call for a professional opinion, and, being answered affirmatively, declined to answer until he had been paid his fee of ten dollars.

The court directed him to answer; but, as he persisted in a refusal, he was fined for contempt of court. This action was appealed from by the physician; but the higher court affirmed the ruling. It was held that, the physician having voluntarily spoken about the condition of the patient, he could not arbitrarily refuse to answer questions naturally connected with his previous testimony. The interesting point whether he could at the outset have refused to answer all questions until he had been paid does not seem to have been decided.

Resurrectionists for Revenue Only.—The Paris papers state that the authorities have been endeavoring for a long time to capture a gang of robbers who have been violating the graves in the cemetery of St.-Ouen-sur-Seine. The robbers eluded the guard until a few days since, when two of them were arrested while stripping jewels from a corpse which they had taken from a grave.

The custom of placing jewelry upon dead

bodies is not a very common one in this country, and the offence of grave-robbing, whenever it is committed, is usually for purposes of dissection or to secure a reward for the return of the corpse, and not to secure buried jewels.

COD-LIVER OIL EMULSION WITH HYPOPHOSPHITES.—The profession is under obligation to manufacturing pharmacists for a palatable preparation of cod-liver oil, in which the nauseating taste and disagreeable effects upon gastric digestion of the pure oil are obviated by administering it in the form of an emulsion. The especial preparation furnished by Messrs. Scott & Bowne has been before the profession for a number of years, and is largely used both in this country and in Europe. It is readily taken by delicate patients, and affords to rachitic or poorly-developed children condensed food in an easily assimilable form.

GOOD ADVICE TO LITIGANTS.—The Court of Errors and Appeals at Trenton, New Jersey, recently advised two litigants to settle their differences out of court. The parties, it seems, had been partners in a drug-business carried on in the city of Newark, and on the dissolution of the copartnership they could not agree as to the division of the firm-property. The ownership of a strip of land back of the store was the bone of contention between them, and they had been fighting for ten years when the court gave them the good advice mentioned. The land was worth about one thousand dollars; but the long litigation had cost the two men many times this amount.

UNWHOLESOME MEAT.—The local Board of Health of New Haven, Connecticut, has had its attention called to a violation of the law by a farmer living at Bethany, a town not far from New Haven. The latter had, it seems, a cow afflicted with a cancer and a tumor, according to the statement made public; yet he sold the animal to a butcher, who slaughtered the cow and used the meat for sausages. This coming to the knowledge of the Board of Health, the farmer was arrested and will have to stand a trial.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.—This body will hold its thirty-seventh annual session in the city of Williamsport, June 2, 3, and 4. The programme must be distributed at least one month prior to the meeting: therefore those who desire to present papers are requested to forward the title and a brief abstract of the subject-matter at an early day to the Chairman of Committee of Arrangements, Dr. T. H. Hillsby, Williamsport.

No voluntary paper is allowed to occupy more than twenty minutes in reading.

WM. B. ATKINSON, M.D.,
Permanent Secretary.

NOTES AND QUERIES.

PARTURITION IN THE NEGRO RACE.

TO THE EDITOR OF THE PHILA. MEDICAL TIMES:

A letter by A. H. in the number for January 9 of your esteemed journal, on "Parturition in the Negro," induces me to call the attention of your correspondent to an elaborate article in the *American Journal of Obstetrics*, vol. viii. (1875–76), by Dr. J. Taber Johnson, of Washington, D.C., on the same subject, which was written at my request, with a view to eliciting whether there really are differences between the negro and white races in the matter of parturition in favor of the former.

In this paper it was shown that while negro women do to a certain extent suffer from the accidents of parturition by which their white sisters are to a much greater degree afflicted, still a peculiar round shape of the pelvic cavity in the negro female and a corresponding limited development of the fœtal cranium in the same race do render parturition, as a general thing, more easy in the negro than in the white race.

Very truly yours,
PAUL F. MUNDÉ, M.D.
30 WEST FORTY-FIFTH STREET, NEW YORK,
January 27, 1886.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 31, 1886, *TO FEBRUARY* 13, 1886.

MAJOR HENRY R. TILTON, SURGEON (Fort Wayne, Michigan).—Granted leave of absence for two months, to commence on or about March 1, 1886. S. O. 8, Division of the Atlantic, February 9, 1886.

MAJOR H. E. BROWN, SURGEON.—Granted leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Department of the Missouri. S. O. 29, A. G. O., February 4, 1886.

MAJOR RICHARD S. VICKERY, SURGEON.—Assigned to duty in connection with the Army and Navy Hospital at Hot Springs, Arkansas. S. O. 24, A. G. O., January 29, 1886.

CAPTAIN R. K. WHITE, ASSISTANT-SURGEON.—Granted two months' leave of absence, to take effect when his department commander may think proper. S. O. 29, A. G. O., February 4, 1886.

CAPTAIN WILLIAM C. SHANNON, ASSISTANT-SURGEON.—Ordered for duty at Fort Warren, Massachusetts, relieving Assistant-Surgeon John M. Banister, who will return to his proper station (Fort Adams, Rhode Island). S. O. 27, Department of the East, February 6, 1886.

FIRST-LIEUTENANT GUY L. EDIS, ASSISTANT-SURGEON.—Ordered for field duty in New Mexico, with troop "K," Eighth Cavalry. S. O. 23, Division of Missouri, February 8, 1886.

FIRST-LIEUTENANT A. R. CHAPIN, ASSISTANT-SURGEON.—Relieved from temporary duty at Fort Robinson, Nebraska, and ordered to rejoin his proper station, Fort Laramie, Wyoming. S. O. 11, Department of the Platte, February 2, 1886.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM JANUARY 31, 1886, *TO FEBRUARY* 13, 1886.

SURGEON H. J. BABIN.—Ordered to U. S. Steamship "Vandalia."

SURGEON W. S. DIXON.—Ordered to Marine Rendezvous, New York City, to relieve Surgeon Babin.

PASSED ASSISTANT-SURGEON ROBERT WHITING.—Ordered to U. S. Steamship "Vandalia."

PASSED ASSISTANT-SURGEON M. H. CRAWFORD.—Detached from the "Shenandoah" on the 8th instant; wait orders.

ASSISTANT-SURGEON C. W. RUSH.—Detached from the "New Hampshire" on the 15th instant, and ordered to U. S. Receiving-Ship "Franklin."

PHILADELPHIA, MARCH 6, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE ON HEREDITARY SYPHILIS.

BY JOHN M. KEATING, M.D.,

Visiting Obstetrician to Philadelphia Hospital, and Lecturer on Diseases of Women and Children, etc.

Reported by WILLIAM A. EDWARDS, M.D., Instructor in Clinical Medicine, University of Pennsylvania; Medical Registrar Philadelphia Hospital.

GENTLEMEN,—At our last meeting we traced the life-history of a syphilitic babe from birth up to the twelfth or eighteenth month.

We have seen that our little patient was probably born with coryza and snuffles, the subject of various skin-eruptions, as the roseolous, papular, and pustular, and with mucous patches on the tongue, lips, and cheeks. We have also seen that the child has a peculiarly old, wizened, senile aspect, with a harsh, unpleasant cry or cough. The child has also exhibited a tendency to marasmus. It is at this time that most syphilitic babes succumb to their inherited diathesis; but, should they survive, a period of latency will commence, extending for a variable period, possibly to puberty or even later. If the disease is to become active, the earlier secondary symptoms are those referable to the special organs and tissues.

Syphilitic ear-affections are frequently met with,—not, however, usually discovered until the child is of an age to appreciate the loss of function. The hepatic structure may be invaded by the disease, shown by an increase in size and weight due to a proliferation of the connective tissue, producing a new fibrous growth and a general hardening. As a consequence, its secretion is markedly impaired. This syphilitic cirrhosis may be the only hepatic symptom that your little patient will present. It is among the most frequent manifestations of hereditary syphilis. You may meet a case of gummatous hepatitis, and in the liver you may find many minute nodules along the fibrous divisions, or you may note but a few large circumscribed tumors. These gummata may be found at birth or at about the tenth or twelfth year, generally the latter. The symptoms of syphilitic hepatitis, especially in an infant, are apt to be masked by the evidences of peritoneal irritation, or even of peritonitis, which may accompany it. The principal symptom would be increase in size of the organ and alterations in the performance of its functions.

An observer of acknowledged worth makes the following remarks in regard to syphilitic hepatitis: "The symptoms are null, or they are identical with those of local and general troubles so often observed in children who have poor or insufficient nourishment. The only physical sign which properly belongs to hepatic syphilis is, when it exists at all, increase in the size of the liver."

Diseases of the osseous system constitute a frequent and important manifestation of the syphilitic diathesis. Taylor's conclusions are about as follows. In the first stage we have a simple hyperplasia of the cells, with irregular deposition of lime salts; in the second, an intensification of this condition; and in the third, a new element, — namely, the abnormal proliferation of all the elements of the tissues, with an infiltration of granulation-tissue into the medullary spaces following the vessels."

The junction of the epiphyses and diaphyses are most affected, as it is here that the growing bone has its most active growth. The bone may be affected before the birth of the child, and the patient will probably be born with a swelling around or in the joint of one of the long bones.

The bones do not seem all to be equally liable to this syphilitic invasion. Those most frequently invaded are probably the radius, ulna, tibia, and femur. Several bones may be affected at one and the same time.

The swelling surrounds the bone and is regular in outline; synovitis may coexist. The process may be arrested in any of its stages; but, of course, if it has gone on to degenerative changes in the bones and cartilages, deformity will be present. Again, when there is no absorption of the new growth, an abscess may result, the bone necrose, and your patient succumb to the prolonged drain on his system. Rarely are the cranial bones involved; when so, the process seldom goes on to abscess-formation and bone-necrosis, but generally is arrested with the osteophytic

formation that you sometimes see on the heads of older children.

Just here I must warn you so that you may be on your guard, so as not to mistake the bone-changes of rachitis for those of syphilis. The differential diagnosis is not always an easy one, and much difference of opinion exists as to their relation. Some authorities consider syphilis as a cause of rachitis. In the case of rachitis, most careful investigation will not elicit any syphilitic prodromes; but you will discover a history of progressive loss of strength, excessive sweating,—as Sir J. Paget tells us, particularly about the head, —diarrhœa and gastro-intestinal disorders, which will make up a picture totally different from that which the syphilitic case will present. Again, the rachitic subject will present you a head the fontanels of which long remain open; the cranial bones will be thickened. Application of the therapeutic test will convince you that specific treatment is of no avail. This hospital almost always has several little patients who well illustrate syphilitic dactylitis, which always produces such marked alterations in the part affected. You may meet with one or two forms, one involving the periosteum and the tissues surrounding a joint, usually the smaller joints, as the fingers or the toes; is almost painless, slow in growth; causes swelling and discoloration of the affected part. The other form is an osteomyelitis with periostitis, and may destroy the part involved. The first variety rarely destroys the tissues invaded, but simply destroys their use for a short time. You may mistake syphilitic dactylitis for various non-specific affections, as paronychia, gout, rheumatoid arthritis, or even for enchondroma or bony exostosis.

The teeth present us interesting studies in hereditary syphilis, more especially as they bear so much on the diagnosis. It is impossible to consider this subject without mentioning Mr. Hutchinson. Indeed, the teeth are sometimes designated by his name. He considers that by far the most reliable among the objective symptoms is the state of the permanent teeth, if the patient be of an age to show them. The temporary teeth do not show such characteristic lesions, and Mr. Hutchinson does not consider that they present any diagnostic points worthy of general reliance. The central upper incisors of the second set are the "test teeth."

"In syphilitic patients, these teeth are usually short and narrow, with a broad vertical notch in their edges, and their corners rounded off. Horizontal notches or furrows are often seen, but they, as a rule, have nothing to do with syphilis." These, gentlemen, are about the words of Mr. Hutchinson, and I consider them of much importance to you as a valuable diagnostic aid.

The cause of these peculiar teeth is still an open question. Mr. Hutchinson is of the opinion that they are due to an arrest in the development of the central portion of the dentine.

Hereditary syphilis may show itself in enlargements of the spleen and liver. Indeed, the spleen seems to be somewhat enlarged in most cases of inherited syphilis at an early date. In many cases the spleen decreases in size as the child grows older, until eventually it is difficult to elicit any evidence of increase in splenic dulness. It would be rare indeed to meet a new growth in the spleen; the process is one of hyperæmia

Enlargement of the liver is generally present, although it is much more apt to resume its normal size than the spleen. Do not forget that the liver is proportionately larger in early life than in an adult. So many causes may operate in enlarging the liver that it is of doubtful diagnostic value.

The pancreas is so inaccessible to the art of physical diagnosis that our clinical knowledge of its diseases is somewhat hazy. A competent observer has noted the fact that in syphilitic fœtuses the gland may be enlarged, presenting proliferation of the connective tissue, which may and generally does cause compression and atrophy and fatty degeneration of the epithelium of the lobules.

Syphilitic disease of the lungs is a point of most engrossing interest. Children may have gummata deposited in the lungs, along the blood-vessel walls and the bronchioles,—usually about half a dozen, and confined to one lung,—or the bronchial glands posteriorly at the root may become enlarged and jeopardize life by pressure. Syphilitic phthisis may develop from a fibro-nuclear growth in the alveolar wall and around the smaller bronchi and pulmonary vessels. It is in this interstitial process upon the bronchial tubes that syphilitic phthisis differs from non-specific

phthisis. The symptoms are difficult to interpret correctly; they are very insidious and gradual in their onset. You may meet with a case of syphilitic pneumonia. You will then find the parenchyma in a state of lobular hepatization, or an entire lobe may be invaded. The part affected is dense and hard, the pulmonary pleura is inflamed and thickened. Cornil describes the process about as follows: the interlobular connective tissue enters into proliferation and presents a large quantity of embryonal cells, the alveolar walls are thick, while the narrow alveoli are livid, and even filled by epithelial cells, which are of the pavement-form in contact with the walls, round in the centre of the alveoli. As the process progresses, the epithelial cells become fatty, degenerated, and subsequently broken down and absorbed, while the embryonal interalveolar tissue rapidly organizes into fibrous tissue. Thus results a small fibrous tumor in which a gumma may develop.

The kidneys may be included in the general syphilitic taint. Bright's disease has been noted to arise coincidently with the outbreak of a well-marked syphilitic eruption. Gumma have been seen in the kidneys of children, or, again, you may find the organ fatty, enlarged, or having undergone degeneration.

The eye-symptoms of congenital syphilis are extremely interesting to the ophthalmologist. Interstitial keratitis will perhaps be the manifestation of the disease that you will most frequently note. Both eyes are generally affected, but one is usually involved first, the other taking part in the process some weeks later. The corneæ may be rendered very opaque, so that the little patient will be barely able to recognize day from night. These opacities will generally in time become absorbed, so that a fair measure of sight may be regained, though in most cases there will always remain some dimness of vision.

Involvement of the nervous system in the syphilitic process may be indicated in many ways,—either by a sudden paralytic seizure due to a rupture of some vessel in the cerebral circulation from specific degeneration of its coats, or the more slow symptomatology of brain-tumor due to a gummatous deposition made manifest by a series of functional and convulsive disorders, of which headache, epilepsy, and special paralyses would be indications.

Your patients will always be solicitous as to the prognosis of the disease, and in order to answer them intelligently it is of course necessary to have clear and correct ideas of its diagnosis. If the interval of infection of the parent or parents before conception have been short, the chances are that the product will have syphilis, and of a grave form. This is more particularly the case if the mother be syphilitic, although there is no reason to suppose that the disease is more virulent when received from the mother than from the father.

If your parturient patient gives you a history of frequent abortions, it is a point worth considering in making up your diagnosis.

The appearance of a syphilitic product is of importance. This has been fully illustrated in my first lecture.

The prognosis is in proportion to the virulence of the symptoms and of their appearance. Late hereditary syphilis is rarely of grave prognostic significance. On the whole, the prognosis of hereditary syphilis is generally favorable, always providing that some serious visceral lesion does not complicate the case. The prognosis when gummata of the brain, liver, or kidneys, for example, arise, is much more grave.

Dr. Blaise discusses the interesting question how far the syphilis of the parents may be manifested in the children in diseased conditions which are not usually classed among the regular manifestations of the disease. He agrees with Fournier that syphilis does so influence children, and that this indirect transmission can only be the result of a deep organic disturbance of nutrition, which may bring into existence new predispositions to disease or awaken old or latent predispositions. He instances the frequent early deaths of children of syphilitic parents, the children dying from simple lack of vitality, without any discoverable cause; the cases of imbecility and idiocy which, without doubt, may be traced back to syphilis of the parents (cases of Fournier and of Tarnier). Hydrocephalus has also been observed (Lancereaux). There have also been noted various forms of failure of development, either general or partial.

You may meet the *syphilis héréditaire tardive* of Fournier, which is that form of hereditary syphilis which shows itself either at puberty or in later years, whether

or not there have been signs of syphilis early in life,—*i.e.*, the *syphilis héréditaire précoce*, which shows at birth or shortly after.

By many, hereditary syphilis has been regarded as a disease of infancy, and all who have not fallen an early sacrifice to it have been regarded as cured and beyond it; and to Fournier again is due the credit for having thrown new light upon late cases of hereditary syphilis.

The treatment of congenital syphilis is an extremely gratifying study. You must treat the mother before and during utero-gestation, endeavoring to eradicate the disease before conception takes place, or, if she be pregnant when you are consulted, endeavor to modify the disease so that the product may have a reasonable chance for life and health. This may be accomplished by the daily use of a pill containing $\frac{1}{12}$ gr. iod. hydrarg. with charcoal. You of course know that to mercury and iodide of potassium we look for our best results in the cases. Remember that the mercury must be in such doses and exhibited in such form as to produce the minimum amount of irritation of the gastro-intestinal tract. In order to prevent abortion, it is well to give it either by inunctions or vaporization. If symptoms of great urgency, select the former. The bichloride of mercury, in doses of $\frac{1}{100}$ of a grain, may be used for a long time with great tolerance. Some practitioners administer it hypodermically. If you give mercury by the mouth, I would advise the combination with small doses of opium or belladonna. After the child is born, you may then treat it either independently or through the milk of the mother. In infants, after giving mercury for a time, you may give half a grain of iodide of potassium dissolved in a tablespoonful of breast-milk. To the mother the child is harmless; to every one else the danger of infection is great. The best method of giving mercury to syphilitic children is by inunctions, or by the oleate of mercury in small amount, and I know of no better means than by spreading mercurial ointment over the child's binder. In this way it will neither cause intestinal derangement, purge, nor affect the gums.

If, however, you desire to give the mercury by the mouth, I would advise mercury with chalk, especially in summer-time. Iodide of potassium may be exhibited in simple watery solution, or you may combine some bitter tonic with it, or, again, the mercury and iodide of potassium may be given together, combined with compound syrup of sarsaparilla. You must, of course, recognize the fact, and explain it to your patients, that the treatment should be continued for a long time after all symptoms have disappeared. In cases where the constitutional treatment must be prolonged, you may use iodine, exhibiting $\frac{1}{2}$ to i gtt. doses, with syrup or emulsion of cod-liver oil, or you may rub the abdomen with a mixture of cod-liver oil and iodine, a drachm of the latter to ten ounces of the former. The further general treatment of a case of congenital syphilis would be the same as in the acquired variety, increasing the dosage in proportion to the age of the individual.

ORIGINAL COMMUNICATIONS.

SOUTHERN FLORIDA: A WINTER SANITARIUM.

Read before the Philadelphia County Medical Society, February 24, 1886,

BY WILLIAM A. EDWARDS, M.D.,

Instructor in Clinical Medicine, University of Pennsylvania; Physician to St. Joseph's Hospital.

THE facilities now offered to Northern tourists and invalids for reaching far-southern climes are so well adapted to comfort and ease of travel that the physician can feel justified in trusting the most delicate cases to the brief railway-journey necessary, which several years ago would have been wearing and fatiguing to the most robust. Indeed, a day and a night on a modern parlor- and sleeping-car is anything but an unpleasant experience, opening each moment new sights and, to the traveller from the North, odd customs of inhabitants of Southern States along the line of travel.

The study of climatology and the selection of sanitaria are of great importance to the physician; but, unfortunately, they usually receive but little attention from the practitioner. How often is the advanced invalid sent far away from his home and all that is dear to him, to be surrounded by strange sights and faces in a strange land, where he has been ordered by a physician who had not taken the trouble to look sufficiently into the matter in order to qualify himself to decide the important question as to which particular climate or

locality was the one best adapted to his patient's case! This has been well stated in a recent address before the American Climatological Association by Dr. John M. Keating, whose personal experience in climatology, gleaned from the climes of all nations, is second to none among us. In considering the matter of a selection of climate, Dr. Keating remarks as follows:

"How often have I met cases of advanced phthisis, away from all the comforts of home and its surroundings, dying in a strange land, sustained only by hope and the fact that they were carrying out the physician's order! I wish that my words could only be made sufficiently impressive to picture to you, as the subject comes up before me, the many sad cases I have witnessed. It is so very easy for the doctor, who possibly knows that all hope is ended and a fatal termination not very far distant, to say to his patient, 'Go to Algiers,' 'Go to Egypt, Australia, or California.' The poor, unfortunate patient is at once inspired with hope. His weakened frame is sustained by the nervous energy which is brought about by determination. The long journey before him is no obstacle. Its discomforts are discounted; and yet he scarcely reaches his destination before nature gives way. The journey to a foreign land requires a degree of strength that is often surprising even to a man in good health. The wear and tear, the vicissitudes of temperature, the character of the cooking, damp sheets, and the hard beds, are much more wearing than most of us imagine. Our Consul-General to Egypt some years ago told me that much of the business of the Consulate was the caring for the baggage of the consumptives who had been sent from home in the last stages of the disease, to run down more rapidly, and possibly die within two or three weeks of their arrival. One of the most shocking sights to the invalid travelling South is to run across the boxes with the death-certificate upon them waiting at the stations for the Northern train. Although I have the greatest possible belief in the value of the change of air and the residence in a suitable climate for those in the early stages of disease, or where predisposition exists, or during convalescence, I am strongly opposed to the method at present adopted of recommending places in a general way, regardless of their suitability and other matters as important as the climate itself. A physician should know thoroughly the place to which he is sending his patient,—be as familiar with it as with the drug he orders in his prescription.

"I met in a fog, on a ship in the China Sea, a young lady who had been recommended by her physician to New Zealand. When she reached there with her family, her condition was such that they determined to bring her home. They returned by way of China, and the dense fog they encountered increased the catarrhal phthisis, which was rapidly breaking down, until she was in a sorry condition. Had she been sent to Aiken or Thomasville, or possibly Bermuda or Santa Cruz, and surrounded by the comforts of life, in an equable climate, within a few hours of her own home, she certainly would have lived longer."

Among the many sanitaria which our varied climate brings within our command, South Florida pre-eminently suggests itself to the medical man in search of a winter-resort with a climate suitable for patients in need of out-door existence and a superabundance of pure, "unprebreathed" air.

The characteristics of the climate of South Florida are *mildness* and *equability;* it lies nearer the equator than any other of the States, yet extremes of temperature are usually unknown, the difference between the maximum of heat and cold being less marked than in any other part of this country. This applies more particularly to the southern part of the State, where frost is seldom found. The usual average daily temperature, it is said, does not vary more than twenty-five degrees, year in and year out.

There is probably no other region in the world where so many elements are present combining to make the climate mild and uniform as in South Central Florida, with Orlando and Winter Park as a centre.

Frosts do occur in Florida, and ice is sometimes found in the shallow waters which are much exposed; but this does not occur every winter, the present season of 1886 being a most unusual experience. For the Floridian south of Lake George, ice and frost would indeed be an unusual sight.

There is no clearly-defined "frost-line;" but the twenty-ninth degree separates the

region of damaging frosts from those that are extremely light.

We should bear in mind the fact that at the 29th or 28th parallel we must not expect the mild winter, the warmth and the sunshine of the tropics: for such we must either seek the tropics themselves or visit Southern California. Changes in temperature, rainy days and cloudy skies, will accompany the same conditions experienced in the North, though to a very much milder extent. These should be expected and prepared for. The absence of blinding snow, of heavy and continuous frosts, of biting winds, will enable the invalid to live in the open air.

If a patient wish to spend the entire winter South, he should choose the well-heated and comfortable hotels of Aiken, Thomasville, or Jacksonville, and remain there until he can be comfortably accommodated farther South.

People do not expect cold weather in the far South, as it comes but rarely, and when it does come the hotels are not prepared for it.

Cyclones and hurricanes never visit the State, nor do earthquakes arise, such as might cause more nervous prostration to a delicate patient in a few short moments than therapeutic skill can undo in months. Nor do the dwellers along the larger streams have to fear an overflow. Natural reservoirs have been constructed for the receipt of the immediate rainfall and for the drainage of the surrounding counties: hence the rise and fall of the rivers are automatically arranged by Nature's engineer. The water gathers in the lakes, these rise in their natural basins, and are again slowly reduced by the rivers.

It must be borne in mind that the entire State is now undergoing a most wonderful upheaval and improvement; marshes are being drained and cultivated, and thousands of acres are yearly meeting the husbandman's plough for the first time; yet, withal, fevers, especially malaria, are not at all frequent, except among those who systematically disobey all hygienic laws, drinking surface-water from creeks and living upon low and badly-drained lands, and continuing upon a basis of living and eating suitable only to cold climates. Some sections of the State are totally exempt from malaria, as those in the vicinity of the sea-shore, and also those in the high, dry pine-lands, with Orlando and its vicinity as an example. It is particularly in Orange County, of which Orlando is the county-seat, that the highest point above the sea is reached on the peninsula. Here you may find the pine-forests and a climate soft and even. This is the climate and the locality that I would particularly recommend for cases of phthisis,—in fact, for all thoracic affections; while for nervous prostration and neurasthenia in the aged it is perhaps the spot *par excellence*.

As an illustration of the mildness and equability of the climate of Orange County, I will quote from the report on meteorology: "In December, 1880, occurred the coldest weather known in Florida for fifteen years. On the coldest day the mercury at St. Augustine fell to 16°, at Jacksonville to 20°, at Palatka to 24°; at Orlando the mercury fell no lower than to 30°."

The writer has met many cases throughout Florida, but particularly in South Central Florida, healthy and vigorous, some of whom are physicians now enjoying large and lucrative practice, who several years ago came to this region as a *dernier ressort*.

It has also been my fortune to meet several men prominent in business and in public life, in fact shaping and giving character to the locality that we are considering, who, some years ago, came to Orlando simply as a last refuge from death.

The county is the most progressive region of a very progressive State. Some years ago—about fifteen—it hardly existed, save as a cattle-range with a very sparse population. Now it numbers 15,425 souls, —a gain since 1880 of 8807.

In this portion of the State is situated the famous lake-plateau, numbering one hundred lakes, along the margins of which people live in perfect health and comfort.

In Orange County no limestone is found; hence the drinking-water may be either supplied by wells or obtained from the clear, deep lakes. Thus the problem of drinking-water is again solved by nature. In some of the counties the residents must depend on rain-water collected in tanks for all their table uses.

The next important step is to consider the personal comfort of our patients during their Southern journey and the creature comforts that they will receive after their arrival.

The months of February, March, and

April, with us, are the most treacherous of the year; in Florida they are replete with all that is most conducive to the welfare of the invalid: this is the time when Florida is at its best.

Everybody coming to Florida by rail must stop at Jacksonville, and I would suggest that this be made the midway point. Let your patient here remain until he has entirely recovered from the wear and tear of his day-and-a-half railway-ride. Here will be found most excellent hotels, good drug-stores and physicians, plenty of amusement and avenues for mental diversion,—a most important, indeed an almost essential, factor in seeking health.

After this temporary breathing-spell, our patient will be ready to proceed farther down the peninsula, either by rail or by steamboat up the St. John River. The latter is the most interesting and instructive. The steamers are large, commodious, and comfortable. Berths can be secured for those patients too weak to sit about the decks and enjoy the ever-changing scenery. Many interesting towns are passed, and along the east bank of the river from Palatka to Little Lake George, a distance of twenty-five miles, fine residences and magnificent orange-groves in excellent cultivation are to be noted. On the opposite side, which is much lower, wild tropical plants and trees grow in profusion.
